ROYAL SANITARY INSTITUTE

LIBRARY REGULATIONS

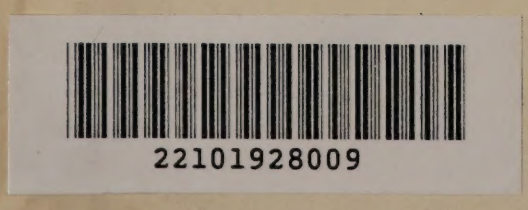
1. Books may be borrowed by Fellows, Members and Associates personally or by a messenger producing a written order. The person to whom books are delivered shall sign a receipt for them in a book provided for that purpose.

2. Books may be sent through the post, or by some equivalent means of carriage, upon a written order. All charges of carriage to the Institute shall be defrayed by the borrower.

3. A borrower may not have more than three volumes in his possession at one time.

4. A borrower will be considered liable for the value of any book lost or damaged while on loan to him, and if it be a separate volume, for the value of the whole work rendered imperfect.
Marking or writing in the volumes is not permitted, and borrowers are requested to call attention to damage of this character.

5. Books may be retained for 28 days. Periodicals may be retained for 14 days. Applications for extension of the loan period must be made in writing before its expiry. No book may be kept longer than 3 months.
New books will not be lent until after the expiration of one month from the date of their having been received by the Institute. The current number of a periodical may not be borrowed.



6. Borrowers retaining books longer than the time specified, and neglecting to return them when demanded, forfeit the right to borrow books until the volume or volumes be returned, and for such further time as may be ordered.
Any borrower failing to comply with a request for the return of a book shall be considered liable for the cost of replacing the book, and the Council may, after giving due notice to him, order the book to be replaced at his expense.
No volume may be reissued to the same borrower until at least seven days have elapsed after its return, neither may it be transferred by one borrower to another.

7. Books may not be taken or sent out of the United Kingdom.

8. Volumes returned through the post must be securely packed in a box, or otherwise protected.

Parcels should be addressed :

VICTORIA R.

Victoria, by the Grace of God, of the United Kingdom of Great Britain and Ireland Queen, Defender of the Faith: To Our Right Trusty and Right Well-beloved Cousin, Walter Stafford, Earl of Iddesleigh, Companion of Our Most Honourable Order of the Bath; Our Trusty and Well-beloved Sir Richard Thorne Thorne, Knight Commander of Our Most Honourable Order of the Bath, Medical Officer of the Local Government Board; Our Trusty and Well-beloved Constantine Phipps Carey, Esquire, Lieutenant-Colonel and Honorary Major-General on the Retired List of Our Army; Our Trusty and Well-beloved Charles Philip Cotton, Esquire; Our Trusty and Well-beloved Michael Foster, Esquire, Master of Arts, Professor of Physiology in Our University of Cambridge; Our Trusty and Well-beloved Thomas Walter Harding, Esquire, Retired Lieutenant-Colonel of Our Auxiliary Forces, with Honorary Rank of Colonel; Our Trusty and Well-beloved Thomas William Killick, Esquire; Our Trusty and Well-beloved William Ramsay, Esquire, Professor of Chemistry, University College, London; and Our Trusty and Well-beloved James Burn Russell, Esquire, Doctor of Medicine, Master of Surgery: Greeting!

Whereas We have deemed it expedient that a Commission should forthwith issue to inquire and report:

1. (1) What method or methods of treating and disposing of sewage (including any liquid from any factory, or manufacturing process) may properly be adopted, consistently with due regard for the requirements of the existing law, for the protection of the public health, and for the economical and efficient discharge of the duties of local authorities; and

   (2) If more than one method may be so adopted, by what rules, in relation to the nature or volume of sewage, or the population to be served, or other varying circumstances or requirements, should the particular method of treatment and disposal to be adopted be determined; and

2. To make any recommendations which may be deemed desirable with reference to the treatment and disposal of sewage;

Now know ye, that We, reposing great trust and confidence in your knowledge and ability, have authorised and appointed, and do by these Presents authorise and appoint, you, the said Walter Stafford, Earl of Iddesleigh, Sir Richard Thorne Thorne, Constantine Phipps Carey, Charles Philip Cotton, Michael Foster, Thomas Walter Harding, Thomas William Killick, William Ramsay, and James Burn Russell to be Our Commissioners for the purposes of the said Inquiry.

And, for the better effecting the purposes of this, Our Commission, We do by these Presents give and grant unto you, or any three or more of you, full power to call before you such persons as you shall judge likely to afford you any information upon the subject of this Our Commission; and also to call for, have access to, and examine all such books, documents, registers, and records as may afford you the fullest information on the subject, and to inquire of and concerning the premises by all other lawful ways and means whatsoever.

And We do by these Presents authorise and empower you, or any three or more of you, to visit and personally inspect such places as you may deem it expedient so to inspect for the more effectual carrying out of the purposes aforesaid.

6225—I. 3,500—Wt. 9302. 9/08. Wy. & S. 3562*r*.

And We do further by these Presents will and ordain that this Our Commission shall continue in full force and virtue, and that you, Our said Commissioners, or any three or more of you, may from time to time proceed in the execution thereof, and of every matter and thing therein contained, although the same be not continued from time to time by adjournment.

And We do further ordain that you, or any three or more of you, have liberty to report your proceedings under this Our Commission from time to time, if you shall judge it expedient so to do.

And Our further Will and Pleasure is that you do, with as little delay as possible, report to Us, under your hands and seals, or under the hands and seals of any three or more of you, your opinion upon the matters herein submitted for your consideration.

And for the purpose of aiding you in such matters, We hereby appoint Our Trusty and Well-beloved Frederick James Willis, Esquire, to be Secretary to this Our Commission.

Given at Our Court at St. James's, the Seventh day of May, One thousand eight hundred and ninety-eight, in the Sixty-first Year of Our Reign.

By Her Majesty's Command,
(Signed) M. W. Ridley.

William Henry Power, Esq., f.r.s.,
To be a Member of the Royal Commission on Sewage Disposal.

VICTORIA R.

Victoria, by the Grace of God, of the United Kingdom of Great Britain and Ireland Queen, Defender of the Faith: To Our Right Trusty and Well-beloved William Henry Power, Esquire, Fellow of the Royal Society, Medical Officer of the Local Government Board: Greeting!

Whereas We did, by Warrant under Our Royal Sign Manual, bearing date the Seventh day of May, One thousand eight hundred and ninety-eight, appoint Our Right Trusty and Right Well-beloved cousin Walter Stafford, Earl of Iddesleigh, Companion of Our Most Honourable Order of the Bath, together with the several Gentlemen therein mentioned, or any three or more of them, to inquire into the treatment and disposal of sewage.

And whereas One of the Commissioners so appointed, namely, Sir Richard Thorne Thorne, has since deceased.

Now know Ye, that We, reposing great confidence in you, do, by these Presents, appoint you, the said William Henry Power, to be one of Our Commissioners for the purpose aforesaid, in the room of the said Sir Richard Thorne Thorne, deceased, in addition to, and together with, the other Commissioners whom we have already appointed.

Given at our Court at Saint James's, the Seventh day of February, One thousand nine hundred, in the Sixty-third Year of Our Reign.

By Her Majesty's Command,
(Signed) M. W. Ridley.

Whitehall, March 18th, 1901.

THE KING has been pleased to issue a Commission, under His Majesty's Royal Sign Manual, to the following effect :—

EDWARD R.

Edward the Seventh, by the Grace of God, of the United Kingdom of Great Britain and Ireland King, Defender of the Faith, to all to whom these Presents shall come, Greeting !

Whereas it pleased Her late Majesty from time to time to issue Royal Commissions of Inquiry for various purposes therein specified :

And whereas in the case of certain of these Commissions, namely, those known as—

The Historical Manuscripts Commission ;
The Horse Breeding Commission ;
The Local Taxation Commission ;
The Port of London Commission ;
The Salmon Fisheries Commission ; and
The Sewage Disposal Commission ;

the Commissioners appointed by Her late Majesty, or such of them as were then acting as Commissioners, were, at the late demise of the Crown, still engaged upon the business entrusted to them :

And whereas We deem it expedient that the said Commissioners should continue their labours in connection with the said enquiries notwithstanding the late demise of the Crown :

Now know Ye, that We, reposing great trust and confidence in the zeal, discretion, and ability of the present members of each of the said Commissions, do by these Presents authorise them to continue their labours, and do hereby in every essential particular ratify and confirm the terms of the said several Commissions.

And We do further ordain that the said Commissions do report to Us under their hands and seals, or under the hands and seals of such of their number as may be specified in the said Commissions respectively, their opinion upon the matters presented for their consideration ; and that any proceedings which they or any of them may have taken under and in pursuance of the said Commissions since the late demise of the Crown, and before the issue of these Presents shall be deemed and adjudged to have been taken under and in virtue of this Our Commission.

Given at Our Court at Saint James's, the fourth day of March, One thousand nine hundred and one, in the First Year of Our Reign.

By His Majesty's Command,
(Signed) CHAS. T. RITCHIE.

THOMAS JOSEPH STAFFORD, F.R.C.S.I.,
To be a Member of the Royal Commission on Sewage Disposal.

EDWARD R

Edward the Seventh, by the Grace of God, of the United Kingdom of Great Britain and Ireland and of the British Dominions beyond the Seas King, Defender of the Faith, To Our Trusty and Well-beloved Thomas Joseph Stafford, Esquire, Fellow of the Royal College of Surgeons of Ireland, Medical Commissioner of the Local Government Board for Ireland: Greeting!

Whereas Her late Majesty Queen Victoria did by Warrant under the Royal Sign Manual bearing date the Seventh Day of May One thousand eight hundred and ninety-eight, appoint Our Right Trusty and Right Well-beloved Cousin, Walter Stafford, Earl of Iddesleigh, Companion of Our Most Honourable Order of the Bath, together with the several Gentlemen therein mentioned, to be Commissioners to inquire into the treatment and disposal of Sewage.

And whereas one of the Commissioners so appointed, namely, Our Trusty and Well-beloved Charles Philip Cotton, Esquire, hath humbly tendered unto Us his resignation of his appointment as one of the said Commissioners:

Now know Ye, that We, reposing great confidence in you, do by these Presents appoint you, the said Thomas Joseph Stafford, to be one of Our Commissioners for the purpose aforesaid, in the room of the said Charles Philip Cotton, resigned, in addition to and together with the present Members of the Commission.

Given at Our Court at Saint James's, the Seventh day of May, One thousand nine hundred and two, in the Second Year of Our Reign.

By His Majesty's Command.
(Signed) CHAS. T. RITCHIE.

REGINALD ARTHUR TATTON, ESQUIRE,
To be a Member of the Royal Commission on Sewage Disposal.

EDWARD R & I.

Edward the Seventh, by the Grace of God, of the United Kingdom of Great Britain and Ireland and of the British Dominions beyond the Seas King, Defender of the Faith, To Our Trusty and Well-beloved Reginald Arthur Tatton, Esquire, Greeting!

Whereas Her late Majesty Queen Victoria did by Warrant under the Royal Sign Manual bearing date the Seventh Day of May, One thousand eight hundred and ninety-eight, appoint Commissioners to inquire into the treatment and disposal of Sewage.

And whereas a vacancy has been caused in the body of the Commissioners appointed as aforesaid by the death of Major-General Constantine Phipps Carey, C.B.

Now know Ye, that We, reposing great confidence in you, do by these Presents appoint you, the said Reginald Arthur Tatton, to be one of Our Commissioners for the purpose aforesaid, in the room of the said Constantine Phipps Carey, deceased, in addition to and together with the present Members of the Commission.

Given at Our Court at Saint James's, the Seventh day of January, One thousand nine hundred and seven, in the Sixth Year of Our Reign.

By His Majesty's Command.
(Signed) H. J. GLADSTONE.

REPORT.

To The King's Most Excellent Majesty:

We, the Commissioners appointed to inquire and report:—

I.—(1) What method or methods of treating and disposing of sewage (including any liquids from any factory or manufacturing process) may properly be adopted, consistently with due regard for the requirements of the existing law, for the protection of public health, and for the economical and efficient discharge of the duties of local authorities; and

(2) If more than one method may be so adopted, by what rules, in relation to the nature or volume of sewage, or the population to be served, or other varying circumstances or requirements, the particular method of treatment and disposal to be adopted be determined; and

II.—To make any recommendations which may be deemed desirable with reference to the treatment and disposal of sewage,

humbly report as follows:—

INTRODUCTION.

1. In this our fifth Report, we propose chiefly to deal with the relative merits of the various methods which are available for the purification of sewage of towns. In a subsequent report we shall deal with the various methods which are available for the purification of trade effluents, when not mixed with sewage.

2. The subject of sewage disposal has been inquired into by the following Committees and Commissions:—

1857. Commission to inquire into the best mode of distributing the sewage of towns and applying it to beneficial and profitable uses.

1862. Select Committee of the House of Commons to inquire into the best means of utilising the sewage of cities and towns of England, with a view to the reduction of local taxation and the benefit of agriculture.

1864. Select Committee of the House of Commons to inquire into any plans for dealing with the sewage of the Metropolis and other large towns, with a view to its utilisation for agricultural purposes.

1865. First Royal Commission to inquire into the best means of preventing the pollution of rivers.

1868. Second Royal Commission to inquire into the best means of preventing the pollution of rivers.

1869. Royal Commission to inquire into and report upon the operation and administration of the sanitary laws outside the Metropolis.

1875. Committee appointed by the President of the Local Government Board to inquire into the several modes of treating town sewage.

1882. Royal Commission to inquire into and report upon the system under which sewage is discharged into the Thames by the Metropolitan Board of Works, whether any evil effects result therefrom, and in that case what remedies can be applied for remedying or preventing the same.

3. The general conclusion of these bodies has been that sewage could only be properly purified by land treatment; and, as a consequence, it has been usual to require local authorities to adopt land treatment.

During recent years, however, certain methods differing from those which were considered by the earlier Commissions have been evolved, and, in view of the difficulty—or even impossibility—which many local authorities experience in obtaining adequate areas of suitable land at reasonable cost, it was considered desirable that these newer methods should be carefully investigated. This led to the appointment of our Commission.

4. One of the first steps taken by us after our appointment was to seek examples of these newer methods. We visited several places which were suggested to us, but in no case was the whole of the sewage of a town being dealt with; in most of the cases no more than a small and a constant quantity of sewage was being treated by the particular process. Moreover, the number of places in which experiments on anything approaching a practical scale were being carried on was very limited. We learnt, however, that for several towns it was proposed to adopt one or other of these newer processes, and we therefore decided to postpone experimental investigation into their merits until the field for observation was more extended.

1630. 5. One of our earliest witnesses, the late Mr. Santo Crimp, an engineer of wide experience, pointed out the danger of basing final conclusions as to a process on the results obtained with experimental plant, and there can be no doubt that inferences so founded must be drawn with caution, especially so when the amount of sewage being dealt with is a fixed quantity each day, and when the experiment does not adequately reproduce the many varying conditions which occur in practice.

Moreover, the weak points in a method of sewage disposal may sometimes only be disclosed after long experience covering a wide range of conditions.

Further, the character of the sewage of different towns varies to so great an extent that it would be unsafe to formulate definite conclusions as to the relative merits of different processes until experience had been gained of their sustained application to different types of sewage.

6. In our first Report we pointed out that at the time of the investigations of the earlier Commissions, the science of bacteriology was in its infancy; those Commissions, indeed, confined themselves almost entirely to a chemical examination of sewage effluents. Since the earlier Commissions reported, a large amount of exact knowledge has been gained concerning the part played by bacteria in various processes of nature and under conditions contrived by man, and it became our duty to study the various questions connected with sewage disposal, not only from a chemical, but also from a bacteriological point of view. This has largely increased our labours.

We have had to initiate and carry out various bacteriological investigations, and apprehending that the work done by earlier Commissions in regard to land treatment did not suffice for our purposes, we have found it necessary to include in our work a systematic and detailed investigation, bacteriological and chemical, of the treatment of sewage on land of various kinds.

PLAN OF WORK.

7. Our investigation has been carried on in the following manner :—

(I) We have held 144 meetings and called before us the following witnesses:—

Name.	Qualification.
Mr. Alfred D. Adrian, C.B.	Assistant Secretary to the Local Government Board (England and Wales).
Mr. A. Murray	Chief Clerk to the Local Government Board (Scotland).
Mr. L. E. H. Deane	Engineering Inspector to the Local Government Board (Ireland).
Mr. R. A. Tatton, M.Inst.C.E.	Chief Inspector to the Mersey and Irwell Joint Committee (1898).
Mr. F. Scudder, F.I.C., F.C.S.	Acting Chemist to the Mersey and Irwell Joint Committee under the supervision of Sir Henry Roscoe, F.R.S.
Mr. W. H. Wilson	Deputy Clerk and Solicitor to the Mersey and Irwell and Ribble Joint Committees.
Mr. W. Naylor, A.M.Inst.C.E., F.C.S.	Chief Inspector of the Ribble Joint Committee (1898).
Mr. Trevor Edwards	Clerk and Solicitor to the West Riding of Yorkshire Rivers Board.
Mr. H. Maclean Wilson, M.D., B.Sc.	Chief Inspector of the West Riding of Yorkshire Rivers Board.
Mr. Theodore Thomson, M.D.	Medical Inspector under the Local Government Board.
Mr. W. Santo Crimp, M.Inst.C.E., F.S.I.	Civil Engineer.
Mr. W. S. Curphey, F.I.C., F.C.S.	H.M. Inspector for Scotland under the Alkali Acts and the Rivers Pollution Prevention Acts.
Mr. Donald Cameron	City Surveyor of Exeter.
Mr. W. J. Dibdin, F.I.C., F.C.S.	Chemist.
Colonel Ducat	Inventor of the "Ducat" filter.
Mr. W. E. Adeney, D.Sc., F.I.C.	Curator and ex-Examiner in Chemistry in the Royal University, Dublin.
Mr. H. Marshall Ward, F.R.S., D.Sc.	Professor of Botany, University of Cambridge.
Dr. G. Sims Woodhead	Director of the Research Laboratories of the Conjoint Board of the Royal College of Physicians (Lond.) and the Royal College of Surgeons (Eng.).
Sir Edward Frankland, K.C.B.	Member of the Commission appointed in 1868 to inquire into the best means of preventing the pollution of rivers.
Mr. W. D. Scott Moncrieff, M.I.M.E.	Engineer.
Mr. J. Garfield, A.M.Inst.C.E.	Engineer in Charge of Sewage Disposal Works at Wolverhampton.
Sir Henry Roscoe, F.R.S., D.C.L., LL.D	Professor of Chemistry in the Owen's College, Victoria University, Manchester, and Scientific Adviser to the Mersey and Irwell Joint Committee.
Mr. Sidney Barwise, M.D. (Lond.), D.P.H. (Camb.)	County Medical Officer of Derbyshire.
Mr. S. Rideal, D.Sc., F.I.C.	Chemist.
Mr. Baldwin Latham, M.Inst.C.E., etc.	Civil Engineer.
Mr. C. J. Whittaker	Chairman of the Accrington and Church Outfall Sewage Works.
Mr. T. Cosham	Representing the Natural Purification Company.
Mr. A. P. Hope, F.C.S.	Representing the "Bacillite" Sewage Purification process.
Mr. H. B. Jagger	Representing the Carbonised Refuse System of Sewage Purification.
Mr. F. Wallis Stoddart, F.I.C., F.C.S.	City Analyst for Bristol.
Mr. W. Brown	Representing the Reeves Chemical Sanitation Company's process.
Mr. W. C. Sillar	Representing the "A.B.C." process.
Mr. Douglas Archibald	Representing the "A.B.C." process.
Mr. H. Wollheim	Representing the "Amines" process.
Mr. W. H. Harrison, M.Sc.	Chemist to the Leeds Sewage Committee.
Mr. W. Eason	City Surveyor of Ripon.
Mr. F. Bagshaw	Borough Surveyor of Harrogate.
Mr. Gilbert J. Fowler, D.Sc., F.I.C.	Superintendent and Chemist of the Manchester Corporation Sewage Works.

Name.	Qualification.
Mr. W. J. Newton, A.M.Inst.C.E.	Engineering Adviser to the Accrington and Church Outfall Sewage Board.
Mr. J. Barnes	Superintendent Chemist in Charge of the Accrington and Church Outfall Sewage Works.
Dr. A. C. Houston	Bacteriologist to Commission.
Dr. G. McGowan	Chemist to Commission.
Mr. G. Chatterton, M.Inst.C.E.	Civil Engineer.
Mr. D. Balfour, M.Inst.C.E.	Civil Engineer.
Mr. W. H. Prescott	Borough Engineer of Reigate.
Mr. Frank Candy	Surveyor and Sanitary Engineer of the International Purification Syndicate.
Colonel Harding	Member of the Commission and Chairman of the Leeds Sewerage Committee.
Mr. G. R. Strachan, M.Inst.C.E.	Civil Engineer.
Mr. Alderman H. F. Hibbert	Chairman of the Chorley Sewage Works and member of the Ribble Joint Committee.
Mr. E. G. Mawbey, M.Inst.C.E.	Borough Engineer of Leicester.
Prof. E. A. Letts, D.Sc., F.I.C., Ph.D.	Professor of Chemistry at Queen's College, Belfast.
Prof. W. A. Herdman, D.Sc., F.R.S.	University College, Liverpool, and Honorary Director of Scientific Work to the Lancashire and Western Sea Fisheries Committee.
The Hon. T. H. W. Pelham	Assistant Secretary to the Board of Trade.
Mr. J. C. Thresh, M.D., D.Sc., D.Ph., F.I.C.	Medical Officer of Health of the Essex County Council.
Mr. T. E. Hill, M.D.	County Medical Officer, Durham.
Mr. G. V. Poore, M.D., F.R.C.P.	Professor of Medicine at University College, London.
Mr. E. E. Klein, M.D., F.R.S.	Chemist and Bacteriologist.
Mr. W. Williams, M.A., M.D., D.Ph. (Oxon), M.R.C.S., F.C.S., etc.	Medical Officer of Health to the Glamorgan County Council.
Dr. P. F. Frankland, F.R.S.	Professor of Chemistry in the University of Birmingham.
Dr. J. A. Voelcker	Consulting Chemist to the Royal Agricultural Society.
Mr. A. F. Firth	Managing Director of Messrs. T. F. Firth and Sons.
Mr. H. Beaumont	Fulling Miller and Finisher.
Mr. J. Crowther	Chairman of the West Riding of Yorkshire Millowners' and Occupiers' Association.
Mr. G. C. Hirst	Woollen Manufacturer.
Mr. J. Bruce	Manager of Tanneries and Currying Works.
Mr. E. Butterworth	Flannel Manufacturer.
Mr. H. A. Foster	Managing Director of Alpaca and Mohair Spinning Works and Manufactories.
Mr. G. Sheard	Woollen Manufacturer.
Mr. W. E. Walker	Tanner.
Mr. Harvey	Tanner.
Mr. J. Stanning Mr. Ross Gemmell Mr. A. J. King	Representing the Calico Printers' Association, Ltd., and Bleachers' Association, Ltd.
Mr. J. H. Mills	Clerk and Surveyor to the Crompton Urban District Council.
Mr. Alderman J. T. Simpson	Chairman of the Halifax Sewage Committee.
Mr. J. Lord	Engineer to the Halifax Sewage Committee.
Mr. Keighley Walton	Town Clerk of Halifax.
Mr. J. Jones	Borough Surveyor of Pudsey.
Mr. W. Hopkinson	Borough Surveyor of Keighley.
Mr. J. E. Sharpe	Engineer and Surveyor of Otley.
Mr. B. Powell	Engineer and Surveyor of Handsworth.
Mr. A. E. Fletcher, F.I.C.	Inspector under the Alkali Acts.
Mr. T. Carter Beeley, J.P.	Mayor of Hyde.
Mr. S. S. Platt, M.Inst.C.E.	Borough Engineer of Rochdale.
Mr. T. Stenhouse, F.I.C., F.C.S.	Public Analyst of Rochdale.
Mr. E. Ll. Morgan, A.M.Inst.C.E.	Borough Engineer of Bolton.
Mr. J. Ashton, F.C.S., F.I.S.E.	Chemist and Manager of the Bolton Sewage Works.

Name.	Qualification.
Mr. R. Johnson	Chairman of the Sewage Committee of Bradford.
Mr. E. A. Brotherton, M.P.	Manager Director of Manufacturing Works.
Mr. D. Howard, F.I.C., F.C.S.	Chemical Manufacturer.
Mr. C. A. Davis	Owner of Dyeworks.
Mr. W. F. Reid, C.E., F.C.S., F.I.C.	Vice-President of the Society of Chemical Industry.
Mr. H. Marshall Mr. C. W. Crossley Mr. P. G. Baldwin Mr. J. Smith	Representing the Halifax Traders' Committee.
Sir Charles A. Cameron, M.D.	Public Officer of Health in the City of Dublin.
Mr. S. Harty, C.E.	Engineer to the Dublin Corporation.
Mr. M. F. Purcell, M.Inst.C.E.	Civil Engineer.
Mr. Forbes Watson	Chemist to Messrs. Guinness, brewers.
Mr. J. C. Bretland, M.Inst.C.E.	City Surveyor of Belfast.
Dr. Lorrain Smith	Professor of Pathology at Queen's College, Belfast.
Mr. George Giles, M.Inst.C.E.	Chief Engineer to Belfast Harbour Commissioners.
Dr. W. S. Squire	Representing the Society of Chemical Industry.
Mr. Alderman Ellis	Tanner.
Mr. Thorp Whitaker	Representing the Bradford Dyers' Association.
Alderman Sir Bosdin T. Leech	Chairman of the Manchester Rivers Committee.
Councillor C. Dreyfus	Deputy Chairman of the Manchester Rivers Committee.
Mr. J. D. Watson, M.Inst. C.E.	Engineer and General Manager to the Birmingham, Tame, and Rea District Drainage Board.
Mr. C. F. Wike, M.Inst.C.E.	City Surveyor and Engineer of the Sheffield Sewage Works.
Mr. J. Haworth, F.C.S.	Chemist of the Sheffield Sewage Works.
Mr. T. Hewson, M.Inst.C.E.	City Engineer of Leeds.
Mr. J. Garfield, A.M.Inst.C.E.	Engineer of the Bradford Sewage Works.
Mr. G. H. Pickles, A.M.Inst.C.E.	Borough Surveyor, Burnley.
Mr. Raymond Ross, F.I.C., F.C.S.	Borough Analyst, Burnley.
Mr. J. Corbett	Engineer of the Salford Sewage Works.
Mr. J. Carter Bell, F.C.S.	Public Analyst.
Mr. J. Arnold	Manager of the Salford Sewage Works.
Mr. James B. Wilkinson, M.D. (Edin.), D.P.H., F.C.S.	Medical Officer of Health, Oldham.
Mr. A. H. Valentine, M.Sc.	Analytical Chemist, Oldham.
Mr. H. T. Bulstrode, M.A., M.D.	Medical Inspector of the Local Government Board
Mr. Phillips	Master of the Brewers' Company.
Mr. H. H. Waller	Vice-President of the West Riding Urban and Rural District Councils' Association.
Mr. R. B. Emsley	Solicitor to the West Riding Urban and Rural District Councils' Association.
Mr. W. B. Pindar	Secretary to the West Riding Urban and Rural District Councils' Association.
Mr. J. S. Martin	H.M. Inspector of Mines.
Captain Anderson	Chairman of the Whitstable Oyster Fishery Company.
Mr. Charles Petrie	Alderman of the City of Liverpool.
Mr. J. Wrench Towse	Clerk of the Fishmongers' Company.
Mr. R. A. Dawson	Representing the Lancashire and Western Sea Fisheries Committee.
Mr. H. Donnison	Representing the Eastern Sea Fisheries Committee.
Mr. H. W. Gibson	Representing the Kent and Essex Sea Fisheries Committee.
Mr. J. Cole	Oyster Merchant, Poole.
Mr. A. L. Scott	Oyster Merchant, Poole.
Mr. A. Brazier	Oyster Merchant, Southwick.
Mr. J. Kennett	Oyster Merchant, Emsworth.
Sir William Pink Mr. St. Barbe	Representing the Southern Sea Fisheries Committee.
Mr. G. H. Baxter	Representing the Chamber of Fisheries.
Mr. J. T. C. Nash, M.D. (Edin), D.P.H.	Medical Officer of Health, Southend-on-Sea.

Name.	Qualification.
Mr. W. J. Bean	Oyster Merchant, West Mersea.
Mr. James Blamey, M.R.C.S.	Medical Officer of Health, Penryn.
Mr. Arthur Newsholme M.D., F.R.C.P. (Lond.)	Medical Officer of Health, Brighton.
Mr. James Niven, M.B.	Medical Officer of Health, Manchester.
Mr. J. H. Barber	Secretary of the Chamber of Fisheries and the London Fish Trade Association.
Mr. William G. Savage, M.D., B.Sc., D.P.H.	Medical Officer of Health, Colchester.
Mr. M. Fitzmaurice, C.M.G.	Chief Engineer of the London County Council.
Prof. Frank Clowes, D.Sc., F.I.C.	Chemist of the London County Council.
Mr. H. Williams, M.D.	Medical Officer of Health, Port of London.
Sir Shirley Forster Murphy, M.R.C.S.	Medical Officer of Health, London County Council.
Mr. C. C. Hutchinson	Counsel to the Lee Conservancy.
Mr. Geo. Corble	Clerk to the Lee Conservancy.
Messrs. Clapham and Fitch	Solicitors to the Lee Conservancy.
Mr. C. N. Tween	Engineer to the Lee Conservancy.
Mr. W. C. Young	Chemist to the Lee Conservancy.
Mr. R. B. Croft	Chairman of the Lee Conservancy.
Mr. E. B. Barnard	Member of the Lee Conservancy.
Mr. H. Nield	Member of the Lee Conservancy.
Mr. R. Phillipson	Secretary to the Thames Conservancy.
Mr. F. A. W. Drummond	Chief Inspector to the Thames Conservancy.
Mr. C. E. Groves	Analytical Chemist to the Thames Conservancy.
Dr. T. J. Browne	Medical Inspector, Local Government Board, Ireland.
Prof. E. J. McWeeney, M.A., M.D., D.Ph.	Bacteriologist to the Local Government Board for Ireland.
Mr. E. W. L. Holt	Scientific Adviser to Department of Agriculture, Ireland.
Dr. Cowie	Representing the South, East, West, and North of Scotland Malt Distillers' Association.
Mr. Allan	
Mr. Thorne	
Mr. Hopkins	
Mr. J. Robertson	
Mr. Doig	
Mr. Grant Glen Grant	
Mr. Fergusson	
Mr. Brown	
Mr. Mustard	
The Duke of Richmond and Gordon	Representing Riparian Owners in Scotland.
Mr. J. R. Findlay	
Mr. W. S. Menzies	
Mr. J. H. W. Grant	
Mr. Herbert Hughes, C.M.G.	Clerk of the Millowners' Association.
Mr. J. Selwyn Rawson	Millowner.
Mr. A. F. Somerville	Chairman of the Sanitary Committee of the Somerset County Council.
Mr. E. Halliwell	Chief Inspector of the Ribble Joint Committee.
Mr. George Reid, M.D., D.P.H.	Medical Officer of Health of the Staffordshire County Council.
Mr. J. Bolton	Manager of the Heywood Borough Sewage Purification Works.
Mr. J. H. Kershaw, F.C.S.	Chemist and Manager of the Corporation Sewage Works, Rotherham.
Mr. K. F. Campbell, M.Inst.C.E.	Borough Engineer of Huddersfield.
Mr. O. J. Kirby	Borough Engineer of Batley.
Mr. J. P. Wilkinson, M.Inst.C.E.	Engineer of the Manchester Sewage Works.
Mr. F. R. O'Shaughnessy, A.R.C.Sc., F.I.C.	Chemist to the Birmingham, Tame, and Rea District Drainage Board.
Mr. Geo. Watson, M.Inst.M.E., A. M.Inst.C.E.	Managing Director of the Horsfall Destructor Co.
Mr. W. F. Goodrich, A.M.Inst.M.E.	London Manager, Messrs. Meldrum Bros., Ltd.
Mr. J. E. Willcox, M.Inst.C.E.	Civil Engineer.

Name.	Qualification.
Mr. H. P. Raikes, A.M.Inst.C.E.	Civil Engineer.
Mr. J. Hunter, F.I.C., F.C.S.	Consulting Chemist.
Mr. J. B. Readman, D.Sc., F.R.S. (Edin.)	Consulting Chemist.
Mr. R. R. Tatlock, F.R.S. (Edin.), F.I.C., F.C.S.	Consulting Chemist.
Mr. J. H. Fullarton, M.A., D.Sc.	Formerly Scientific Adviser to the Fishery Board for Scotland.
Mr. Jas. Hendrick, B.Sc., F.I.C.	Public Analyst for the Counties of Aberdeen, Banff and Nairn.
Mr. Stevenson Macadam, F.I.C., F.C.S.	Analytical and Consulting Chemist.

(II) We have, by means of circular letters, obtained a large amount of assistance from many scientific men who have had special experience in regard to the subject of sewage disposal.

(III) A number of local authorities have carried out experimental investigations in association with the Commission, and have been good enough to furnish us with monthly records of the results of their experiments. These towns are as follows :—

Birmingham.	Leeds.	Rotherham.
Burnley.	Manchester.	Salford.
Heywood.	Oldham.	Sheffield.
Huddersfield.		

The reports furnished by these authorities are printed with the evidence. In each case the officers responsible for the local investigations were called before us to give evidence.

(IV) We have put under the systematic observation of our own officers a number of sewage farms and sewage works of different types.

The officers' reports on their observations of artificial processes are issued with this report as Appendix III. Their reports on the sewage farms were issued as an Appendix to our Fourth Report.

(V) We have carried out the following special investigations :—

Place at which the experiment was carried out.	Object of experiment.
Accrington	(*a*) For the purpose of ascertaining the relative difficulty of treating the same tank liquor, diluted and undiluted, on contact beds and on percolating filters. (*b*) To compare the purification effected in each instance by these two types of filter, under similar conditions in the one and in the other case.
Dorking	(*a*) For the purpose mainly of comparing septic tank liquor, precipitation liquor, and settled sewage derived from the same sewage, as to their amenability to subsequent oxidation by filtration. (*b*) To compare the reduction of suspended matter in the same sewage effected by the different processes of tank treatment, and to ascertain the quantities of sludge produced in each case. (*c*) Removal of suspended matter from percolating filter effluents. (*d*) Reduction in number of intestinal organisms in filtrates by means of sterilising agents, and comparison of the results obtained by this method with the effect of filtration through sand. (*e*) Comparative values of deep and shallow filters. [*See also* Ilford.]
Exeter (Belle Isle)	Digestion of sludge in septic tank. [*See also* Ilford.]
Guildford	For the purpose of ascertaining whether, by the addition of "oxychloride" solution to septic tank liquors, the unpleasant smell actually developed by such liquor may be destroyed without impairing the ability of the filter, subsequently dealing with the liquor so treated, to effect the requisite purification.
Hendon	Sterilisation of effluents.
Ilford	(*a*) Digestion of sludge in septic tank. (*b*) Comparative values of deep and shallow filters.

At some of these places channels have been provided along which the effluent has been allowed to flow, the main object being to ascertain whether effluents liable to bring about undesirable changes in the condition of a stream into which they are discharged can be clearly distinguished by chemical test from those which do not.

(VI) We have personally visited a large number of sewage works.

8. We wish to express our great indebtedness to the several local authorities, and to the many gentlemen from whom we have received assistance. Their names are far too numerous to mention.

Appendices to Report.

9. The following volumes are presented as appendices to this report :—

(I) The Evidence of Witnesses.

(II) A Summary of the Evidence.

In preparing this report we found it necessary to make a summary of the evidence.

The plan which was followed was to divide the subject up into chapters such as sewage, storm-waters, sedimentation tanks, septic tanks, standards, and so on, and then to sub-divide each chapter.

The evidence given on questions of primary importance was thus very briefly summarised and brought together.

We think that this summary may possibly be of general utility and we have therefore decided to publish it, but of course the evidence itself should be consulted by anyone wishing to make a complete study of the subject.

(III) Reports on the observations of artificial processes at the following places :—

Accrington.	Halton.	Maidstone.
Andover.	Hampton.	Newton le Willows.
Calverley.	Hartley Wintney.	Normanton.
Caterham.	Hendon.	Oswestry.
Chorley.	Hendon (Ducat filter).	Prestolee.
Clifton.	Horfield.	Rochdale.
Exeter (Main Works).	Kingston-upon-Thames.	Slaithwaite.
Exeter (St. Leonard's).	Knowle.	Withnell.
Guildford.	Little Drayton.	York.

(IV) Reports on the special investigations, mentioned on page 7, at Accrington, Dorking, Exeter, Guildford, Hendon, and Ilford.

Memorandum by Mr. Frye upon experiments carried out at Oldbury on the treatment of the sewage of that town.

Memorandum by Dr. McGowan as to measuring strength of sewage.

Report by Dr. McGowan and Mr. Frye on the estimation of the work done by filters which have been under the observation of the Commission.

Report by Dr. Houston on laboratory experiments on the biological purification of sewage.

Report by Dr. Houston on the biological character of B. coli in sewage and sewage effluents.

Reports by Dr. Houston on the results of the bacteriological examination of sewage and effluents from the sewage works at Bradford, Leeds, Manchester, and Ilford.

Report by Dr. Houston and Dr. McGowan on the sterilisation of the Lincoln water.

(V) Reports by Mr. Baldwin Latham, M.Inst.C.E., and Mr. R. A. Tatton, M.Inst.C.E., upon the effect of rainfall on the flow of sewage.

(VI) A report by Professor Letts and Dr. Adeney on the pollution of estuaries and tidal waters. In regard to this we may refer to paragraph 116 of our fourth Report, which was as follows :—

> "In connection with the question of standards as regards offensive putrefaction and injury to fish, we may state that much work has already been done, both in this country and abroad. We have therefore thought it desirable that the results of this work should be collected and collated. Mr. E. A. Letts, D.Sc., F.I.C., Ph.D., Professor of Chemistry at Queen's College, Belfast, and Mr. W. E. Adeney, D.Sc., Vice-President of the Institute of Chemistry, Curator and Examiner in Chemistry in the Royal University, Dublin, have kindly arranged to do this and to report to us on the question how far these results may suffice to show the conditions under which tidal rivers would become, (*a*) a nuisance in consequence of offensive putrefaction or (*b*) injurious to fish, either in consequence of the diminution of oxygen or the presence of poisons. The results so collected will, we hope, be of considerable use in enabling each Rivers Board to deal with waters under its jurisdiction."

To this report is appended a Paper by Mr. Gilbert J. Fowler, D.Sc., F.I.C., on the effects of discharge of septic tank sludge into a tidal estuary.

(VII) A copy of a circular letter on the question of standards for sewage effluents, and of the replies which were sent to us by chemists and others.

(VIII) Reports by Mr. W. Somerville, D.Sc., Mr. T. H. Middleton, M.A., M.Sc., and Dr. J. A. Voelcker upon experiments on the manurial value of sewage sludge.

Terms of Reference.

10. The first paragraph of the Terms of Reference requires us to state how (*a*) sewage, (*b*) sewage and trade effluents, and (*c*) trade effluents alone, may be properly treated or disposed of having regard to the requirements of

I.—The existing law.
II.—Public health.
III.—Economy and efficiency.

The second paragraph requires us to report by what rules, in relation to varying circumstances or requirements, should the particular method to be adopted be determined.

These terms open up a wide field of inquiry, and the second paragraph involves intimate study of various methods of treatment, many of which are new, under a very large number of different conditions.

GENERAL CONCLUSION.

11. Before dealing in detail with the numerous questions involved in our inquiry, we think it will be convenient that we should at once state our general conclusion on the question contained in the first paragraph of our Terms of Reference.

We are satisfied that it is practicable to purify the sewage of towns to any degree required, either by land treatment or by artificial filters, and that there is no essential difference between the two processes, for in each case the purification, so far as it is not mechanical, is chiefly effected by means of micro-organisms. The two main questions, therefore, to be considered in the case of a town proposing to adopt a system of sewage purification are, first, what degree of purification is required in the circumstances of that town and of the river or stream into which its liquid refuse is to be discharged; and, second, how the degree of purification required can, in the particular case, be most economically obtained.

The choice of a scheme must depend on a number of considerations which will be discussed later, but we may here state that we know of no case where the admixture of trade refuse with the sewage makes it impracticable to purify the sewage either upon land or by means of artificial processes, although in certain extreme cases special processes of preliminary treatment may be necessary.

PLAN OF REPORT

12. We propose to divide this Report into the following parts :—

		PAGE
Part I.	Preliminary Treatment of Sewage.	
	Introductory Remarks	11
	Strength of sewage as affecting purification	15
	Preliminary processes for the removal of suspended matters	18
	General observations	18
	Screening	18
	Grit or detritus tanks	19
	Sedimentation tanks	19
	Septic tanks	21
	Chemical precipitation	30
	Observations as to the relative cost of various preliminary processes	36
	Observations on the choice of tank treatment ...	43
Part II.	Purification of Sewage by artificial filters.	
	Introductory Remarks	47
	Extent to which suspended matters should be removed before filtration	48
	Contact beds	51
	Percolating filters	70
	Relative cost of contact beds and percolating filters ...	101
	Relative efficiency of contact beds and percolating filters ...	107
	Concluding observations	117
	Table of analytical results obtained at Accrington, Burnley, Heywood, Huddersfield, Leeds, Manchester, Oldham, Sheffield, and other places which have been under observation	120
Part III.	Purification of sewage by treatment on land.	
	Introductory remarks	137
	Comparison of effluents from land and from artificial filters	137
	Volume of sewage which can be treated on land ...	143
	Cost of land treatment	152
	Comparison of cost of land treatment and treatment by artificial filters	158
Part IV.	Sludge.	
	Methods of disposal of sewage sludge	159
	Manurial value of sewage sludge	183
	Sludging of mill dams	189
Part V.	General.	
	Effect of trade effluents on sewage purification	192
	Nuisance from smell at sewage works	195
	Observations on choice of a method of sewage treatment ...	202
	Treatment of storm water sewage	204
	Separate and combined systems of sewers	211
Part VI.	Standards and Tests.	
	Standards for sewage effluents	217
	Tests for sewage effluents in relation to standards ...	221
Part VII.	Pollution of estuaries and tidal waters	225
Part VIII.	Summary of conclusions and recommendations.	
	Previous Reports	226
	Present report	229
	Central authority	234

PART I. PRELIMINARY TREATMENT OF SEWAGE.

INTRODUCTORY REMARKS.

13. Sewage generally may be said to consist of a mixture of saline matter in solution and nitrogenous and carbonaceous organic matter in solution and suspension together with a certain amount of grit and mineral matter. The objects to be aimed at in its purification are the removal of the suspended matters and the oxidation of the remaining organic matter and ammonia.

There is a considerable amount of evidence to show that the oxidation of the organic matter during its passage through filters or land is chiefly a biological process, but as to the exact nature of the action which takes place very little is known.

One of our chemists, Mr. Colin Frye, carried out a * series of experiments at Leeds, in which he showed that, although a mature filter could not appreciably oxidise sewage sterilised with corrosive sublimate, it could oxidise sewage which had been sterilised with steam. Further, that a sterile filter could not appreciably oxidise sterile sewage.

We may also refer to some experiments which Dr. Houston, our bacteriologist, made during the year 1903. (Report by Dr. Houston on laboratory experiments on the biological purification of sewage: contained in Appendix IV.)

These experiments seem to suggest that the presence of such non-sporing bacteria as B. coli, B. proteus, etc., are not *essential* to purification, and that the work may be performed by other micro-organisms.

They also show that, although a filter may contain initially an enormous number of B. coli, if the liquid passing on to the filter contains none of these micro-organisms, this microbe rapidly disappears from the effluent, although the filter may still be able to support the life of many other bacteria. It is therefore to be inferred that sewage filters, when working properly, are not likely to provide suitable breeding grounds for pathogenic bacteria, although they allow a certain number of such bacteria to pass through them.

14. As regards the fermentative changes which occur in the purification of sewage, Dr. Adeney has made a large number of valuable experiments. His results have been published from time to time in the Transactions of the Royal Dublin Society, and in the proceedings of the Royal Irish Academy, and a connected account of the work is included in the † Report, which he and Dr. Letts have presented to the Commission on the Pollution of Estuaries and Tidal waters.

Dr. Adeney founds the following general conclusions on his work :—

General Summary.

" In the foregoing pages the chemical changes, which occur in a polluted water during so-called self-purification under aerobic conditions, and the laws underlying them, have been traced and established ; and this has necessitated the discussion in minute detail of a large amount of experimental evidence of a varied character. A brief summary of the results arrived at, apart from experimental details, may therefore prove of some convenience to those interested in the subject.

" The most important change which occurs in an unpolluted water, when it is mixed with sewage or other water-borne refuse matters, is the more or less rapid absorption of its dissolved oxygen.

" The absorption may be effected in three different ways :—(1) The polluted water, from its own state of total or comparative de-aeration, reduces the aeration of the unpolluted water by simple dilution ; (2) the polluted water may contain directly and easily oxidisable substances, which on becoming mixed with the unpolluted water will cause a more or less rapid loss of its dissolved oxygen ; (3) the organic constituents of the sewage, which are not directly oxidisable (and they usually form the greater portion of the organic substances in it), and the ammonium compounds, are oxidised through the agency of water bacteria, and thus indirectly cause a loss of dissolved oxygen.

" These possible causes of de-aeration are enumerated in the order in which they would in all probability take effect under natural conditions. The first is obvious, although its importance has not been sufficiently recognised. Its effect can easily be differentiated from the other two, if the amount of dissolved oxygen, or as it is generally termed, the degree of aeration of the polluted water, be first determined, and this can be done without difficulty either by a gasometric or volumetric method.

* For a description of these experiments *see* our Second Report, Cd. 1178 [1902].
† *See* Appendix VI.

"The second cause of de-aeration is equally obvious, although its importance has also not been sufficiently realized. Such experiments as those recorded in Tables 34, 35, 35A, 36, and 37 prove that directly oxidisable bodies, from the rapidity with which they absorb oxygen, constitute a greater danger to the aeration of the water with which they become mixed than do indirectly oxidisable substances. Hence it is necessary to know the rate of absorption of oxygen caused by them as well as by indirectly oxidisable substances.

"It is impossible to foretell the influence of these two causes of de-aeration from any information derivable from the ordinary methods of chemical analysis. It is, however, possible to do so by means of the aeration method, and the foregoing pages have been largely devoted to a description of that method, and of the experimental investigation upon which it is based.

"A study of indirect oxidation by this method has shown that it is a physiological process analogous to the respiratory process of higher vegetable systems; but that it is only one, although the principal one, of a number of physiological processes concerned in the self-purification of a polluted water under aerobic conditions.

"It is unnecessary to discuss these in detail. It is sufficient for the study of polluted waters to recognise the possibility of processes of digestion (by enzymes), and to regard the remainder as together exercising one function, viz., the synthesis of the constructive materials required for the growth and multiplication of the bacteria, and at the same time to remember that there must result from these synthetical processes waste or by-products, which may be regarded as excretory substances.

"The chemical changes which are produced by the above processes may collectively be termed fermentative changes for convenience of reference.

"Experiments with samples of sewage and of polluted waters, of various descriptions, have been made, and it has been found that when they were severally mixed with unpolluted water in small proportions, within the limits of fouling, the fermentative changes which follow exhibit a definite and regular sequence. The organic matters first suffer complete fermentation, the products of change being carbonic acid, water, ammonia, and organic substances possessing the chemical and physical properties of the humus of cultivated soils, and of the organic substances to be found in all unpolluted natural waters, especially in those from upland surfaces.

"A second stage of change subsequently ensues, in which these humus matters and the ammonium compounds are further fermented, the resulting products being carbonic acid, nitric acid and water.

"The inorganic products of the first stage of fermentation result from the action of the respiratory process, and possibly also of enzymes; and the humus-like substances are waste products from the synthetical processes.

"It is a point of interest to note that free nitrogen has not been observed amongst the products of the fermentation of organic substances in water under aerobic conditions, although it does undoubtedly occur amongst the products of fermentation in percolating filters even when the conditions therein are wholly aerobic. It is a question, no doubt, of intensity of oxidation. The filter presents conditions for an extremely rapid and intense oxidation; while water in large bulk, owing to the sparing solubility of oxygen in it, can only allow a sluggish oxidation to proceed in it.

"Experiments with distilled water solutions of simple organic substances of known composition have shown that the respiratory process is one of simple oxidation, and that the organic matters affected by it are completely oxidised to the inorganic products, carbonic acid, ammonia and water. The oxidation may either be complete step by step as the fermentation proceeds, or only partial at first but finally complete, according to the chemical properties of the substances undergoing fermentation.

"In the simple solutions employed in these experiments, it was evident from the composition of the organic substance dissolved in each and from the ratio of the carbon dioxide formed to oxygen absorbed, on its complete fermentation, that the oxygen was almost, if not entirely, taken up by the respiratory process. Other experiments, however, have shown that it is quite possible under certain exceptional conditions as to the composition of the fermenting substances, for the synthetic processes to take up relatively considerable quantities of oxygen. Whether oxygen is or is not taken up by these processes appears to be a question of composition of the fermenting substance, as might be expected. In ordinary cases, however, of polluted waters, the composition of the polluting substances generally appears to be such that during their fermentation the absorption of oxygen is practically confined to the respiratory process.

"Enzymic action is intimately associated with the respiratory process in the fermentation of many organic substances. The chemical changes induced by them are principally hydrolytic, and the products are generally simplifications of the original body; and these undergo further fermentative change. Only in the case of urea do they bring about a complete change to the ultimate products, carbon dioxide and ammonia.

"Sometimes enzymic changes occur with almost explosive velocity; *e.g.*, asparagin, when present in the fermenting water, is hydrolysed with extreme rapidity, the whole of it being converted into aspartic acid and ammonia at the very commencement of the fermentation, the hydrolysed product, aspartic acid, then undergoing complete fermentation.

"In other cases, enzymic change may proceed extremely slowly, very much more so than the other fermentative changes which may be going on in the same water. Urea when present in some polluted waters is an example of this.

"There are some other substances which may occur in polluted waters, *e.g.*, native albumins and fats, which require to undergo enzymic change before they can be readily fermented by water bacteria.

" The chemical changes which are brought about by the respiratory process and by enzymes may be regarded as yielding a continual supply of energy to the bacteria. They effect the complete oxidation of 70 to 80 per cent. of the organic substances originally present in the polluted water.

" The new material resulting from the synthetical process accounts probably for about 5 per cent., or even less, and the waste products for the remaining 15 to 25 per cent.

" As regards possible relationships between the volume of carbon dioxide formed to oxygen absorbed in a polluted water, it is obvious there can be no very definite one, especially when the water contains directly and easily oxidisable substances, *e.g.*, sulphides, etc., in addition to indirectly oxidisable ones. As a matter of fact, however, in the case of most waters polluted by fresh sewage, a fairly constant relationship has been observed, the ratio of carbon dioxide to oxygen being approximately as 1 : 1. If the sewage be putrefactive and contain sulphides, the ratio may be much less, *e.g.*, the ratio for the septic tank liquor employed for the experiments recorded in Table 39 is as 1 : 1·3.

" After the completion of the fermentation of the organic matters, a second stage of change, as already noted, sets in, and during it the products of the first stage, that is, the ammonium compounds and the humus matters, undergo further fermentation. As a result the former are completely oxidised to nitric acid and the latter more or less completely to carbon dioxide and nitric acid. The point of interest and importance in this stage of fermentative changes is the influence of the humus matters on the oxidation of the ammonium compounds.

" Laboratory experiments have shown that they not only accelerate the fermentative changes, but that their presence is necessary for the oxidation of the ammonium compounds to nitric acid. When they are entirely absent, the oxidation is not carried under ordinary conditions beyond nitrous acid.

" When the ammonium compounds are present in slight excess of the humus matters, both may be completely fermented, the inorganic products being carbon dioxide, water and nitric acid.

" The changes which humus matters may undergo when in excess of the ammonium compound appears to be very variable. For example, when fresh, a portion of their carbon is readily oxidised to carbon dioxide, and then, if unassociated with compounds of ammonia, they cease to undergo much further change.

" The volume of oxygen actually absorbed in the second stage of fermentation does not bear a constant ratio to the oxygen theoretically equivalent to the nitrous and nitric oxides formed. The volume may be greater than the theoretical, in the proportion of 10 : 8·14 (Table 19, Experiment 1 and 1*a*), if humus matters are wholly absent ; or less, *e.g.*, 10 : 13·5 (Table 19, Experiment 2), if these are present in large quantities and are freshly formed.

" Where, as in ordinary cases of polluted tidal waters, humus matters are unlikely to be present in any but small proportions, the volume of oxygen required for the oxidation of the ammonia to nitric acid can be calculated with sufficient accuracy from the equation :—

$$2\ NH_3 + 4\ O_2 = N_2O_5 + 3\ H_2O.$$

" On comparing together the changes which progressively occur in the two stages of fermentation which have been described, it becomes evident that the oxidation of ammoniacal nitrogen to nitrous and nitric acids constitutes the central feature of the second stage, just as the oxidation of organic carbon to carbon dioxide constitutes the central feature of the first stage. It may be concluded, therefore, that the products nitrous and nitric acids of the one stage are the analogues of the product carbon dioxide of the other stage. The first stage of fermentation may consequently be termed the carbon-oxidation stage, and the second the nitrogen-oxidation stage. These terms have the advantage of emphasising a fact which it is necessary to keep in mind in dealing with the subject of water pollution ; it is that the sequence of the chemical changes, which occur during self-purification under aerobic conditions, takes place in accordance with thermo-chemical principles.

" A classification of the substances which may occur in polluted waters may be made, based on their behaviour towards the dissolved oxygen of the water, as follows :—

(1) Directly oxidisable substances.
(2) Indirectly oxidisable substances.

" These latter may be further sub-divided, according to their fermentative properties into—

(*a*) Carbon oxidisable substances, that is, most known organic substances except antiseptics.
(*b*) Nitrogen fermentable substances, that is, the waste products from a first stage fermentation, and ammonium compounds.

" Not only do the fermentative changes in a polluted water follow a definite and regular sequence, but the relationship between the oxygen absorbed and the products formed, and between both of these and the quantities of polluting matters originally present, are quantitative according to the following law :—The quantities of oxygen absorbed, and of products formed, on the completion of each stage of aerobic fermentation, is constant for similar volumes of the same polluted water, provided that the dissolved oxygen is in excess of the fermenting matters.

" It must be granted from the above brief description of the fermentative changes which occur in a water during self-purification under aerobic conditions, that the significance of the presence of indirectly oxidisable substances in water depends not upon their exact quantity and chemical composition, but upon their fermentative properties and on the rate at which they will absorb oxygen from the waters with which they are mixed The same remark applies with equal force to directly oxidisable substances."

" It must also be granted that the methods which are at present employed for the analysis of sewage and of sewage effluents, which were originally worked out for the analysis of potable waters, do not afford information of this kind. The aeration method has consequently been proposed for the purpose. As may be gathered from the perusal of pp. 67–91 it is possible to determine by its means the rate of absorption as well as the total absorption, of oxygen which a sewage or sewage effluent is capable of setting up when mixed

in small proportions with unpolluted river or tidal water, during direct oxidation as well as during both stages of indirect oxidation. From the description of the method given on p. 96, it will be seen that several modifications in working can be adopted according to the object in view, that is to say, whether it be desired to study the fermentative changes step by step in their entirety, or simply to determine the rate of, or total, absorption of oxygen during them. The modifications required for the latter purpose can be so simply operated that untrained persons can be taught to carry them out without difficulty.

"Another phase of the subject of the self-purification of slightly polluted waters, and a scarcely less important one, is the rate at which the dissolved oxygen in such is replenished from the atmosphere under natural conditions, when it is being absorbed by polluting matters. It is obvious that definite information is required on this question before it will be possible to formulate standards of impurity for the protection of river and tidal waters from over-pollution.

"Experiments have been described which afford some fairly trustworthy information on this subject. The results of these experiments were quite unexpected, since they show that the slow rate of re-aeration of large volumes of de-aerated tidal water under calm weather conditions is not due to the slow process of mixing by thermal current or of diffusion of the dissolved gas after it has been taken up in solution by the surface layers of the waters exposed to the air. On the contrary, it has been shown that the slowness of re-aeration is due to retardation of the process of solution at the water's surface, and that when oxygen has become dissolved at the surface from the atmosphere, it is drawn with comparative speed through the water, apparently by some unexplained process of gravitational streaming. It has also been shown that long columns (6 feet) of de-aerated fresh or sea water enclosed in narrow glass tubes of small bore are comparatively quickly re-aerated when the surfaces of the columns were kept continuously broken, either by a mechanical stirrer or by a slow current of air delivered by an inlet tube dipping a little below the surface.

"It has, furthermore, been found from these experiments that the aeration of the sea water columns was effected much more rapidly than that of the fresh water columns, and that the dissolved gases showed practically no tendency to accumulate in the surface layers of the sea water columns, but passed almost as quickly through them as they were dissolved, with the result that the degree of aeration of the water is found to be nearly uniform throughout the length of the column, if it be tested at different depths at any time during the process of aeration; while in the case of the fresh water columns the dissolved gases did show a tendency to accumulate in the upper layers, and did not pass so rapidly to the lower layers."

15. Dr. Fowler, Professor Frankland, Mr. Harrison, Dr. Letts, Dr. Reid, Mr. Stoddart, Dr. W. Owen Travis and many others have also carried out numerous experiments with a view of elucidating some of the scientific questions involved in the purification of sewage, but notwithstanding the fact that a considerable amount of exact knowledge has been gained as the result of the experimental investigations which have been already made, there are many questions in regard to which our knowledge is exceedingly limited.

As regards the actual disposal of sewage on a practical scale, Colonel Harding and Mr. W. H. Harrison, at Leeds; Dr. Fowler, at Manchester; Mr. J. D. Watson and Mr. F. R. O'Shaughnessy, at Birmingham; Messrs. Willcox and Raikes, and Dr. George Reid at Hanley, Newcastle-under-Lyme, and elsewhere; Mr. A. H. Valentine and Dr. J. B. Wilkinson, at Oldham; Messrs. Raymond Ross and G. H. Pickles, at Burnley; Mr. Joshua Bolton, at Heywood; Mr. J. H. Kershaw, at Rotherham; Mr. K. F. Campbell, at Huddersfield; Mr. J. Carter Bell, at Salford; Mr. C. F. Wike and Mr. J. Haworth, at Sheffield, and others have carried out many valuable experiments in regard to certain methods of purifying sewage. These gentlemen have placed before us all their results, and have been most liberal in assisting us in every possible way.

16. As regards our own work we have, in an earlier paragraph, explained the general scope of our investigations.

Throughout our inquiry we have endeavoured to gain such knowledge as would enable us to pass from the stage of broad qualitative observation to one of exact quantitative statement, but in regard to many matters this transition is not at present practicable, and, therefore, we can only comply in general terms with the terms of reference which directed us to state "by what rules, in relation to the nature or volume of sewage, or the population to be served, or other varying circumstances or requirements, should the particular method of treatment and disposal to be adopted be determined."

The circumstances of different places are of endless variety and there are many varieties of treatment, any one of which will be successful, if properly carried out. The main question to be determined in each case is which of these methods will be cheapest, having regard to the local circumstances.

We propose to discuss various methods of disposal in some detail, and then to indicate, in broad terms, the considerations which should be borne in mind in the selection of a method of treatment for any particular case.

STRENGTH OF SEWAGE AS AFFECTING PURIFICATION.

17. The composition of different sewages varies to a large extent, and it is important to consider how strength of sewage, as affecting purification, may be measured. The amount of filtration necessary to produce an effluent of any given standard of purity varies, to a wide extent, with different sewages.

The variations in strength of the sewage of different towns depend chiefly on the amount and nature of the water supply; the extent to which the houses are provided with water closets; whether a separate system of sewers is provided for storm waters; and what trade effluents (if any) are admitted into the sewers. Dr. Fowler has pointed out that a fairly accurate idea of the strength of sewage, as affecting purification, may be arrived at by measuring the number of gallons of sewage per head per day arriving at the outfall and making allowance for the other factors, while other witnesses have suggested that the usual tests, such as "oxygen absorbed", are sufficient. 22735.

18. Where, however, a more exact measure of strength is needed, we are inclined to think not only on theoretical grounds, but also as the result of experience, that this can at present best be obtained by ascertaining the amount of dissolved oxygen taken up during the complete, or practically complete, oxidation of the organic and ammoniacal matter in the sewage. 25578.

The purification of sewage is to a large extent a process of indirect oxidation through the agency of bacteria, and one of the chief things required to be known about any particular sewage is how much oxygen is required for its complete oxidation. The rate at which the sewage will take up oxygen is also a factor of importance, in that it furnishes information as to the character of the organic matters.

The dissolved oxygen test is a biological process, and it differs from the ordinary tests—such as oxygen absorbed from permanganate—in that it takes account of practically the whole of the organic matter, and not merely that of a particular kind.

The amount of oxygen which a sewage can take up is, however, only an approximate measure, for purposes of purification, of its strength, as some constituents of sewage are oxidized by filters or land more readily than others, and the proportion which they bear to the total organic matter varies largely in different cases.

19. To determine the amount of oxygen which a sewage requires for its oxidation, a definite quantity of the sewage is allowed to remain in contact with a known excess of oxygen until it is completely oxidised, and the oxygen remaining over is then measured. This can be done either:

(*a*) By diluting the sewage largely with good tap water, estimating the oxygen in solution in a portion of the mixture, and allowing the remaining portion to stand in a bottle which is filled completely and shut off from all access of air. At least two months must be allowed for this, after which the oxygen remaining in solution is determined. The difference represents the oxygen used up.

(*b*) By keeping the sewage, without diluting or diluting only very slightly, continuously aerated in a bottle containing a measured excess of air. Dr. Adeney, who has suggested this plan, has found it to be very much more rapid than the first.

20. A serious disadvantage in the use of the dissolved oxygen test as a measure of the strength of sewage is that it requires, even with the more rapid method suggested by Dr. Adeney, a comparatively long time to oxidize the organic matter completely by dissolved oxygen. From the results of a considerable number of laboratory experiments with method (*a*), we thought that a period of about two months might be generally taken as sufficing for the oxidation of nearly all the oxidisable matter, excluding (to some extent,

at least) cellulose and fat. Later results, however, appear to show that this may be too short a time under ordinary conditions of experiment. Though we have not made enough observations on the point to speak definitely, we are satisfied that the oxidation of cellulose and fat in diluted sewage, under the aerobic conditions of our experiments and at ordinary temperature, is slow*. In practice, however, there are but few instances of the treatment of *crude* sewage on biological filters, and the amounts of cellulose and (probably) of fat which are present in the liquids usually treated (settled sewage, septic tank liquor, and precipitation liquor) are relatively small.

By method (*b*) and by making use of a mechanical shaker attached to a suitable gas apparatus, Dr. Adeney† succeeded in oxidizing strong septic tank liquor by means of atmospheric oxygen, without any dilution with water, while he followed the course of the reaction by determining at different intervals of time the quantity of oxygen required by known volumes of the liquor. In this way he reached the nitrification stage of the process in twelve days. The method is thus a great advance, as regards time required, upon the dilution method.

Recently Dr. Adeney has invented an ingenious apparatus for carrying out the dissolved oxygen absorption test, by which the rate of absorption of oxygen as well as the total amount of oxygen taken up can be readily measured. It is described on p. 438 of Appendix VI.

21. With a view to ascertaining whether the dissolved oxygen absorption test bears any more or less constant ratio to other and more rapid tests, Dr. McGowan, our chemist, has made a number of observations.

He gives figures to show that the amount of dissolved oxygen which a sewage would take up during oxidation can be arrived at, with a fair degree of accuracy, by a calculation based on the " oxygen absorbed " figure and the figures of analysis of the ammoniacal and organic nitrogen.

A copy of Dr. McGowan's Memorandum is printed in Appendix IV.: the following extract shows the formulæ which he suggests:—

"By applying the results given in Table A it would appear that the relative 'strength' of a sewage liquor can be arrived at rapidly, with a fair degree of accuracy, by estimating the ammoniacal and organic nitrogen and the 'oxygen absorbed" from strong acid permanganate *at once* and *in 4 hours* at 27°C. (80°F.), and afterwards making use of one of the following alternative formulæ:—

(1)		
Column 9.	For *Sewages.*	(Ammon. + Organic N.) × 4·5 + (Oxygen abs. in 4 hrs. × 6·5).
	For *Septic Tank Liquors.*	,, ,, ,, + (,, ,, × 6·5).
	For *Precipitation Liquors.*	,, ,, ,, + (,, ,, × 6·0).
(2)		
Column 10.	For *Sewages.*	(Ammon. + Organic N.) × 3·0 + (Oxygen absorbed in 4 hrs. × 8·0).
	For *Septic Tank Liquors.*	,, ,, ,, + (,, ,, ,, × 8·0).
	For *Precipitation Liquors.*	,, ,, ,, + (,, ,, ,, × 7·5).
(3)		
Column 8.	For *Sewages,*	(Ammon. N. + 4·5) + (Oxygen absorbed in 4 hrs. × 8·0).
	For *Septic Tank Liquors.*	,, ,, + (,, ,, ,, × 7·5).
	For *Precipitation Liquors.*	,, ,, + (,, ,, ,, × 7·5).

"The variations in the individual ratios given by the same kind of sewage liquor in Table A are too great to allow of this method of arriving at their 'strengths' being more than approximate. Probably the variations would have been less marked if all the long aerations had been carried out in mercury-jointed bottles, and if the small quantities of gases evolved had been allowed for. Further experiments will, however, settle the point."

* One part of cellulose, by weight, requires only 1·2 parts of oxygen for its complete oxidation; one part of fat requires nearly 6 parts of oxygen. Tri-palmitin $C_3H_5(OC_{16}H_{31}O)_3$ is taken here to represent fats generally.

† The Pollution of Estuaries and Tidal Waters. Report to the Royal Commission on Sewage Disposal, by Professor Letts and Dr. Adeney, p. 101 *et seq.* See Appendix VI.

As regards Dr. McGowan's suggestion, we consider that until the method of calculation which he proposes has been compared with the results of direct experiment on a larger number of *different* sewages, no statement can be made as to its precise accuracy. We have, however, found it convenient to use the method in the preparation of this Report in order to bring results at different places into line.

In later sections we shall frequently define the strength of a sewage or sewage liquor by a number. This number is intended to represent the number of parts, by weight, of dissolved oxygen which 100,000 parts of the liquid would take up during the oxidation of the oxidizable matter contained in such liquid. It will not, however, have been arrived at by direct experiment, but by a calculation, according to the first of the formulæ suggested by Dr. McGowan, and it must therefore only be regarded as approximately representing what it is intended to represent.

22. As bearing on the question of strength of sewage as affecting purification, we may refer to our experiments at Accrington.‡

A double contact bed plant filled with rather fine and graded material was provided in duplicate. On one set of contact beds, septic tank liquor was treated at the rate of 80 gallons per cube yard per day; on the other set, the same septic tank liquor diluted with an equal volume of tap water was treated at double the rate. The percentage purification was slightly greater in the case of the contact beds treating the weaker liquor.

Two exactly similar percolating filters, 9 feet deep, filled with coarse material, were also provided.

On one filter, septic tank liquor was treated at the rate of 100 gallons per cube yard per day; on the other filter, the same septic tank liquor diluted with an equal volume of tap water was treated at double the rate. In this case the percentage purification was slightly greater with the filter treating the stronger liquor.

The differences in the percentage purification were, however, in both plants so small that we think it may be taken broadly that, within ordinary limits of concentration and volumes treated, it is the amount and nature of the organic impurity present which mainly determine in practice the ease or difficulty of purification; in other words, that, within practical limits, mere dilution does not affect the size of the filtering plant which is necessary. Of course if the dilution is so great as to cause water-logging of the filters, their purifying power would be seriously diminished, and this statement would not hold good.

The Accrington experiments are dealt with more fully on pages 110 to 117 of this Report.

---

‡ *See* Appendix IV. for a full account of these experiments.

PRELIMINARY PROCESSES FOR THE REMOVAL OF SUSPENDED MATTERS.

General Observations.

23. The evidence which we have received and our own experience show that it is generally more economical to remove from the sewage, by a preliminary process, a considerable proportion of the grit and suspended matter, before attempting to oxidize the organic matters on land or in filters.

It is true that at Leeds, Sutton, Hampton, Hendon (the Ducat filter), Market Drayton (the Ducat filter), and elsewhere, crude sewage has been satisfactorily purified in filters with almost complete absence of nuisance, but at most of those places, this plan has been abandoned because of the rapid choking of the filters.

As regards the treatment of crude sewage on filters, we have ourselves made detailed observations at the following places :—

Hampton.	Maidstone.
Hendon.	Newton-le-Willows.
Little Drayton.	Withnell.

Reports on these observations are published in Appendix III.

There are also many cases in which crude sewage has been passed over land, but the evidence shows that land treatment of crude sewage is liable to give rise to nuisance by the accumulation of solids on the surface of the land. Moreover, in some cases these solids are apt to form an impervious layer which interferes with the aeration of the soil, and so impairs the efficiency of the treatment.

Screening.

24. On arriving at the works the sewage is usually passed through coarse screens for the purpose of removing the grosser suspended matters, such as sticks, cloths, paper, corks, etc.

The removal of such suspended matters is almost essential where the sewage has to be pumped, and in other cases it is usually considered an advantage.

Although the amount of suspended matter which is removed by coarse screens bears only a small proportion to the total suspended matter, the screenings have some manurial value, and there is usually no difficulty in getting farmers and others to take them away.

The screens in use are of various kinds, and some are provided with automatic apparatus for clearing them.

Experiments with fine screens were carried out at Leeds,* with a view to ascertaining whether it was practicable to remove a large proportion of the total suspended solids in this way.

With a screen of a mesh of 30 to the inch, however, rather less than 10 per cent. of the total of the suspended matters was removed.

The use of fine screens is always attended with difficulty as they choke readily, and the experience of Leeds seems to show that where tank treatment is provided as a preliminary process, the cost of fine screens would not be justified.

In the circumstances obtaining at Birmingham, Mr. Watson prefers not to screen the sewage, but to allow the whole of the suspended matter to flow, with the sewage, to the first sludge tanks. The sludge itself is screened, to remove the grosser solids, before it is disposed of on land.

---

* Report on experiments in Sewage Disposal, June, 1905, by Col. T. W. Harding and Mr. Harrison.

Grit or Detritus Tanks.

25. Most of the witnesses whom we have examined favour the removal of the heavy suspended matters, such as grit or road detritus, as a first operation, and our own observations have shown that in most circumstances it is desirable to provide tanks for this purpose.

These tanks are usually designed so that the speed of flow will allow the mineral matters to settle out of the sewage, while the bulk of the organic suspended matters are carried forward.

The extent to which the heavy matters need be settled out of the sewage as a first operation depends in some measure on the subsequent treatment which is to be adopted.

Where septic tanks are to be used which will only be cleaned out at long intervals of time, fairly thorough preliminary settlement of grit is generally desirable. The removal of the sludge which has accumulated over a long period in a septic tank is, as a rule, a matter of difficulty, as the sludge is often so thick that it cannot be pumped unless sewage or water is mixed with it. Much mineral detritus in the sludge increases this difficulty.

We also consider that in the case of septic tanks from which a portion of the sludge will be removed periodically, preliminary settlement of the mineral detritus is, as a rule, desirable. Tanks to be used in this way are generally provided with sludge channels formed in the concrete floor. If the sludge to be drawn off contains much mineral detritus, it will not flow to the channels but will remain in heaps at the side.

In the case of a very small works (flow of sewage up to, say, 10,000 to 15,000 gallons per 24 hours) where septic tanks are used for the preliminary process, the provision of grit or detritus tanks which require constant sludging may necessitate more labour than would otherwise be the case, and in such circumstances it may be more economical to allow everything to go forward into the septic tank. Although the presence of the mineral detritus in the general tank sludge would make the sludging of the tank a more difficult operation, the saving of labour between the intervals of sludging would probably more than balance the extra cost of removing the sludge.

Where precipitation or sedimentation tanks are to be used, and especially if the district is sewered on the combined system, it will, we think, generally be found better to settle out a considerable proportion of the mineral detritus before allowing the sewage to pass into the tanks. The necessity of giving thorough preliminary settlement of the grit is not, however, in these cases of so great importance, for the presence of grit in sludge renders the latter more amenable to pressing and drying.

Sedimentation Tanks.

26. All tanks are sedimentation tanks, but it is convenient to limit the expression to tanks in which the sewage is allowed to settle, without the aid of chemicals, and from which the sludge is frequently removed.

In some cases the tanks are allowed to stand full, and the supernatant liquid is drawn off by a floating arm. In other cases the sewage is allowed to flow through the tanks slowly, but continuously.

Quiescent Sedimentation.

27. Experiments which were carried out at Leeds and Sheffield showed that, with the sewages of those cities, quiescent settlement for two to three hours was sufficient to remove a large proportion of the suspended solids entering the tanks, and to produce a fairly good tank liquor.

No precise rule, however, can be laid down as to the period of quiescence which is required to effect a given reduction of the suspended solids.

Certain kinds of sewage contain more solids which settle very slowly, than other kinds.

For example, a large proportion of the solids in sewages which contain brewery or tannery waste, or wool scouring liquor, are difficult to settle.

To maintain this form of settlement in a highly efficient condition, the deposit in the tank must be removed after every first or second filling.

Continuous Flow Sedimentation.

28. We have had experience of this method of sedimentation at Clifton, Halton, Oswestry, and Dorking. The following table shows the settlement effected at these places:—

Place.	Shape of Tank.	Dimensions of Tank.	Time allowed for settlement.	Rate of flow per minute in inches.	Solids (in parts per 100,000) reduced from
Clifton - -	Rectangular	39′ × 5′ × 4′.	5·3 hours.	1· 7″	49 to 24.
Halton - -	„	25′ × 12′ × 6′.	15·5 „	0·66″	17·7 to 10·7
Oswestry - -	„	70′ × 15′ × 4′ 6″.	4·1 „	3·40″	32·0 to 15·8
Dorking - -	„	18′ 6″ × 4′ 6″ × 4′ 9″.	11·9 „	0·31″	20·8 to 10·1

The amount of settlement does not depend alone on the period of flow, but also on various other factors, such as the shape of the tank, the nature of the suspended matter in the sewage, and the length of time during which the tank is used without being cleaned.

If the tank is not cleaned out frequently, the deposited sludge begins to ferment and the gas produced carries suspended matter with it, as it rises to the surface of the liquid.

As a general rule, if the filters to be used are constructed of fine material, on which it would be undesirable to put a large amount of suspended matter, we consider that the period of flow should be from 10 to 15 hours, and that the tanks should be cleaned out at least once a week.

Before either kind of sedimentation is adopted, the nature of the suspended matter in the sewage which is to be dealt with, and the rate at which it settles, should be considered.

Should Sedimentation Tanks be used in series or in parallel?

29. It would usually be more advantageous to use continuous flow sedimentation tanks in parallel than in series, for the following reasons:—

With tanks of ordinary dimensions, the minimum rate of flow is obtained where the tanks are used in parallel.

As a rule, after a certain percentage of the suspended solids has settled out of a sewage, little further advantage is gained by continuing the same tank treatment, the suspended solids remaining in the supernatant liquid being of low specific gravity, and depositing very slowly unless quiescent settlement is given. In practice, therefore, so soon as this maximum quantity of solids is settled out as a result of continuous flow settlement, little advantage is obtained by passing the liquid through another tank at a similar rate.

If sedimentation tanks are used in series, there is a natural tendency to allow the last tank in the series to run too long without being cleaned out. The result in such a case is that the sludge, lying at the bottom of this tank, even though small in amount, begins to ferment with the formation of gas bubbles, which carry suspended matter up into the liquid.

There is rather more difficulty in cleaning tanks which are used in series than those used in parallel, owing to the fact that the first tank in a series is usually found to contain very thick sludge, which may, in some cases, have to be mixed with sewage before it can be got to flow into the sludge main; while in the last tank the sludge is very thin and watery. At a large works, however, where there are special facilities for removing and dealing with dense sludge, such as would accumulate in the first tank, this difficulty would not be serious.

Our experience with continuous flow settlement tanks used in series has been obtained chiefly at Halton, and, with continuous flow settlement tanks used in parallel, at Oswestry and Shipley. As the same arguments apply to the settlement of precipitated sewage, however, we may also adduce the results of our observations at Kingston, Maidstone, and Hendon, for the use of tanks in series, and at Horfield, for the use of tanks in parallel.

It is desirable to use quiescent settlement tanks in parallel, in order that the period of actual quiescent settlement (*i.e.*, apart from filling or drawing off) should be as long as possible.

Nuisance.

30. Settlement of sewage by sedimentation does not give rise to serious smell during the time the tanks are actually at work. When the tanks are sludged, there is considerable smell, and since tanks used for quiescent settlement have to be sludged more often than those in which there is a continuous flow, there is more liability to recurring nuisance in the former case.

In the case of tanks used for settling domestic sewage, there is only slight local smell during the process of settlement. We have had practically no experience of the sedimentation of sewage containing brewery or tannery refuse in quantity, but in such cases the smell would, no doubt, be markedly increased.

Septic Tanks

31. The notion that the solid matter of sewage would be digested by passing the sewage through a sealed tank is by no means novel, but it does not appear to have had any extensive practical application until Mr. Cameron, who held the office of City Surveyor of Exeter, proposed the adoption of the "septic tank treatment" for that city.

At that time it was claimed that the septic tank possessed the following, among other, advantages:—

That it solved the sludge difficulty, inasmuch as practically all the organic solid matter was digested in the tank.

That it destroyed any pathogenic organisms which there might be in the sewage.

That sewage which had passed through a septic tank was more easily oxidized than sewage from which the solids had been allowed to settle, either with or without the aid of chemicals, in tanks which were frequently cleaned out.

32. As regards the first of these claims, it is now clearly established that, in practice, all the organic solids are not digested by septic tanks, and that the actual amount of digestion varies to some extent with the character of the sewage, the size of the tanks relative to the volume treated, and the frequency of cleansing.

At Huddersfield, Mr. Campbell estimated that about 38 per cent. of the solids were converted into gas or digested; at Leeds, Mr. Harrison put the figure at about 30 per cent.; at Manchester, Dr. Fowler says that possibly, though not certainly, about 25 per cent. of the total suspended matter is digested or converted into gas; at Sheffield, Mr. Haworth puts the digestion at 32·9 per cent., while at Birmingham, Messrs. Watson and O'Shaughnessy say that the figures available indicated a digestion of not more than 10 per cent. of the suspended matter entering the tanks. 21,633 21,994 22,923 23,611 24,985

From careful observations, extending over two years, which we made at Exeter and Ilford, we found that, without allowing a correction for colloidal matters, the digestion at Exeter was about 25 per cent., and at Ilford about 30 per cent.

The sewages of both places were domestic in character: the Ilford sewage was of average strength ; and the Exeter sewage about two-thirds as strong. In each case the tank was sufficient to enable it to hold a day's (24 hours) flow, and no sludge was removed from either tank during the experiment. A detailed report of the experiment is contained in Appendix IV.

33. As regards the second claim, we find as a result of a very large number of observations that the sewage issuing from septic tanks is, bacteriologically, almost as impure as the sewage entering the tanks.

34. As regards the third claim, the evidence which we received was conflicting. Some witnesses stated that septic tank liquor was more easily treated than sewage from which the solids had been settled, either with or without the aid of a precipitant, while others expressed a contrary view.

The point is one of great importance in the purification of sewage, and we therefore thought it desirable to investigate it somewhat exactly.

After visiting several places, the Dorking sewage was selected as a suitable domestic sewage with which to experiment, and the Dorking Urban District Council were good enough to grant us the requisite facilities for making the experiment at their works.

For the purpose of the experiment, three identical percolating filters were constructed. One was fed with settled sewage, one with sewage which had been subjected to chemical precipitation, and one with septic tank liquor.

35. The experiment, which was under the supervision of our own resident chemist, Mr. Eric H. Richards, and was carried on for over a year, conclusively proved that in the case of an ordinary domestic sewage, such as that at Dorking, septic tank liquor is not more easily oxidized on its passage through filters than the other liquids.

The experiment is fully reported on by Mr. Richards in his Report, which is published in Appendix IV.

The results of careful experiments previously carried out at Rochdale by Mr. Platt, at Leeds by Mr. Harrison, at Huddersfield by Mr. Campbell, and at Sheffield by Messrs. Wike and Haworth, at all of which places the sewage contains trade effluents from manufacturing processes, agree with our Dorking results.

36. It must, therefore, be said that some of the more important claims which were originally advanced in favour of septic tank treatment have not stood the test of experience. At the same time, we think that in certain circumstances the adoption of this method of treatment, as a preliminary process, is efficient and economical.

Suspended Solids issuing from Septic Tanks.

37. The settlement of the suspended solids in septic tanks is not usually very thorough, and the evidence shows that at many places the liquor issuing from the tanks contains on the average from 15 to 20 parts of suspended solids per 100,000.

At the places which we have had under observation the average figures were as follows :—

SEPTIC TANKS.

Name of place.	Character of sewage.	Suspended solids in original sewage. Parts per 100,000.	Suspended solids in tank liquor. Parts per 100,000.		Time of passage through tanks.
			Average.	*Remarks.*	
Accrington - -	Strong domestic sewage	38·93	19·40	14·3 shortly after sludging	Once in 42 hours.
Andover - - - -	Domestic, containing some brewery refuse.	15·80	11·10	8 months after incomplete sludging.	Once in { 19·3 hours (dry weather flow). 13·1 hours (max. flow).
Caterham - - - -	Exceptionally strong domestic	42·10	22·2	1 month after sludging	Apparently 48 hours' flow, when 3 out of the 4 hourly sets were drawn.
Exeter (Main Works) -	Strong domestic	37·2	12·50	18 months after sludging	Once in 11·5 hours (dry weather flow).
Exeter (St. Leonards) -	Weak domestic	26·10	8·40	12 months after complete sludging.	Once in { 17·8 hours (dry weather flow). 8·6 hours (maximum flow).
Hartley Wintney - -	Domestic, with a considerable proportion of brewery refuse.	{ 20·10 (dilute winter sewage) 32·7 (dry summer sewage) }	15·10	After 3½ years without sludging	Once in 31·7 hours (dry weather flow).
Guildford - - - -	Strong domestic, containing a large proportion of brewery refuse.	42·1	15·9	Tank full of sludge	Once in 36·7 hours.
Knowle - - - - -	Domestic	19·40	8·42	——	Once in { 15·2 hours (dry weather flow). 3·2 hours (max. flow).
Prestolee - - - -	Weak slopwater sewage	5·42	3·17	After 4½ years without sludging	Once in 22 hours (dry weather flow).
Rochdale - - - -	Strong manufacturing sewage, containing large quantity of wool scourings, etc.	36·70	5·30	Tank in use for only 3 months	Once in 30 hours.
Slaithwaite - - -	Dilute domestic (mainly slopwater)	10·70	7·10	After 5½ years without sludging	Once in 13·6 hours (dry weather flow).
York - - -	Weak domestic	21·2	5·3	Two tanks, one in use 18 months and the other 6 months.	Once in 26 hours.

It must also be observed that it is generally impracticable to maintain the amount of suspended solids issuing from a septic tank at an approximately uniform level for any length of time ; and, that the amount has a tendency to increase seriously as time goes on.

For example, at Burnley it was found that the suspended matter varied from 15 parts per 100,000, after a few weeks' working, to 35 parts per 100,000 at the end of six months ; at Huddersfield the amounts were 6·6 parts per 100,000 at the commencement and 23·3 parts per 100,000 at the end of eleven months ; at Leeds, from January to June, 1903, starting with a perfectly clean tank, the suspended solids averaged 12·2 parts per 100·000, and from July to December, 1904, the average was 24·1.

The variation in the amount of the suspended solids in the tank liquor increases the difficulty of maintaining the effluent from the filters at a constant level of purity, and the amount of tank liquor which can be properly dealt with on the filters tends to decrease as the amount of the suspended solids in the tank liquor increases.

Cleansing of Septic Tanks.

38. There is no doubt that the longer a tank is run without cleaning, the less *volume* of sludge there will be per million gallons of sewage treated. Digestion, of course, plays some part in this, but only a small part compared with the settling together of the finely divided septic sludge lying at the bottom of the tank. The sludge from a septic tank which is cleaned out at short intervals of time may contain something like 90 to 95 per cent. of water, while, if the tank is allowed to run for, say, two years, the water in the sludge may be only 80 to 85 per cent., or even less. It is obvious that this makes a great difference in the volume of the sludge to be dealt with, provided that it can be removed from the tank in the semi-solid form and without having to be mixed with sewage or water to make it run through the valves.

There is also evidence to show that sludge which has remained in a tank for a long period, say, a year or more, is in some cases less offensive than sludge which has been there for only two or three months. At Birmingham, Leeds, Exeter, and other places this was found to be the case, though, on the other hand, at Guildford, where there is a considerable amount of brewery waste in the sewage, the septic sludge had a very offensive smell when removed from a tank which had been in operation for a period of twelve months.

39. From the point of view of sludge disposal alone, it would be generally advisable to allow septic tanks to run for considerable periods of time before cleaning out, either wholly or partially. There are, however, two other important considerations to be taken into account, viz. :—

The amount of suspended matter issuing in the tank liquor, which greatly increases as time goes on, and

The fact that at a large sewage works it would usually be less easy to deal with very large quantities of sludge at long intervals of time than with smaller quantities at short intervals.

Constant conditions as regards the amount of suspended solids in the liquor issuing from the tank should be aimed at, and from this point of view frequent partial removal of the solids would usually be desirable ; but our experience points to the conclusion that there can be no definite rules as to how long a septic tank should be run without cleaning, and that it must be left to the manager of each works to see that the suspended solids issuing from the tank do not increase to such an extent as to have an injurious effect upon the filters or upon the quality of the filtrate. The point at which injury to the filters or deterioration of the filtrate will occur will largely depend upon the nature and strength of the sewage, the kind of filter used, the size of the material in the filter, and the rate of filtration. At Accrington, for instance, something like fifteen parts of suspended matter in the septic tank liquor can be put upon the coarse percolating filters, without any danger of clogging, whereas at Manchester and Burnley, this would be too much for the contact beds.

Again, the successful working of some forms of fine percolating filter (*e.g.*, that at Friern Barnet), depends upon the time allowed for the drying of the sludge on the surface of the material between two applications of tank liquor. A tank liquor containing, say, 10 parts of suspended matter per 100,000, might be conveniently treated on a filter of this kind, if the delivery were made once every three days; but if it were made once every day, the sludge caught on the surface of the filter would probably not have dried sufficiently to allow of its being scraped off before the next delivery was made.

40. Although the point is not one in regard to which any general rules of a precise character can be laid down, we are inclined to think that in the case of small sewage works, constructed to serve populations of, say, 100 to 10,000, it would be best that septic tanks should be allowed to run, without being cleaned out, so long as the suspended matter in the tank liquor showed no signs of affecting the filters detrimentally, provided that the tanks were never allowed to become more than one-third full of sludge.

In the case of a sewage works constructed to serve populations from 10,000 upwards, we think it would probably be advisable partially to clean out septic tanks at short intervals of time, care being taken as far as possible to remove only the best digested portion of the sludge.

41. With regard to the question whether it is advisable *entirely* to remove the sludge from septic tanks when these are cleaned out, the evidence and our own observations seem to show that this is not advisable. Experiments at Leeds, Rochdale and Dorking have shown that the changes which sewage liquor undergoes in a septic tank are of minor importance as regards subsequent filtration, but the following considerations must be borne in mind :— Cameron, 1902; Harrison; Campbell; Valentine; Wilkinson; Raymond, Ross and Pickles; Watson; Harding; Fowler.

In a septic tank which is to be cleaned out there is always a considerable amount of sludge which has had little time to undergo digestion. If possible, therefore, this part of the sludge should be left in the tank.

One of the main uses of a septic tank is that it has the effect of equalising the sewage as regards strength, and of keeping the character of the liquor uniform.

If a septic tank is cleaned out completely, some weeks may pass before the fermentation of the sludge is in full progress again. It was found, at Birmingham, that, if some of the sludge is left in a septic tank at the time of cleaning, fermentation is hastened when the tank is re-started. At Rochdale, Mr. S. S. Platt has shown that the same effect can be produced by filling a clean and empty tank with septic liquor (from another tank) before any fresh sewage is allowed to pass into it.

Where sludge is removed from septic tanks at long intervals of time, and especially where it is disposed of by burial in the ground, it is of great importance to carry out the operation in dry weather. The success of the plan of disposing of the sludge by burial in the ground depends very largely upon the rapidity with which the sludge can be covered over in the trenches, and this is governed by the state of the ground and the atmospheric conditions prevailing at the time.

Rate of Flow through Septic Tanks.

42. For the reasons which we have already given we consider that the main objects in passing sewage through septic tanks must be looked upon as being :—

The settlement of the suspended matter in the sewage ;

The digestion of as much sludge as possible ; and

The equalisation of the sewage as regards strength.

43. The most advantageous rate of flow, therefore, is that which gives the maximum settlement and the maximum digestion of sludge, without producing any serious nuisance from smell. It is impossible, however, to lay down any given rate or rates of flow through septic tanks for all sewages, for the following reasons :—

The suspended matter in sewage differs as regards ease of settlement and rate of fermentability at different places. The suspended matter in a strong slopwater sewage, for instance, settles more easily and takes longer to putrefy than the suspended matter in a strong domestic sewage derived from water-closets.

The degree of settlement depends also upon the form of tank adopted. The passing of a sewage through a Dortmund tank, for instance, would no doubt give better settlement than would be the case if a plain rectangular tank were used, but there would probably be less digestion of the sludge.

The qualities necessary in the septic tank liquor may vary at different places. At one place where septic liquor was to be treated upon percolating filters of coarse material, a larger quantity of suspended matter might be allowed to pass away in the liquor, without danger to the filters, than at another place where the liquor was to be treated upon fine-grained filters. Again, where it was of the utmost importance to have as little sludge to deal with as possible, and where the filters could be washed and re-made cheaply, the digestion of the sludge would be of greater importance than the settlement of the suspended matter ; whereas, at another place where ample facilities for dealing with sludge existed and where filtering material could only be obtained at high cost, the reverse would be the case.

The question of smell arising from the septic liquor during its distribution would also assume greater or lesser importance at different places. Generally speaking, very slow passage through the tank tends to increase the risk of nuisance from smell.

In a number of cases, owing to long sewers or to the use of the sewers for storage, the sewage is already in what is called a "septic" condition when it reaches the sewage works.

44. The rate of flow through a septic tank is consequently a matter in which the needs of each place require to be taken into account: but from general experience and a consideration of the evidence, we think it may safely be said that at few places should the sewage remain more than 24 or less than 12 hours in a septic tank. We think therefore, that the total tank capacity, excluding the stand-by * tanks for storm water, should be equal to the total daily dry weather flow. In designing a sewage works where septic tanks were to be adopted, never less than two tanks should be provided, and these should be so constructed that one tank alone could be used at a time. If better settlement became necessary, it might be found that this could be effected by using the tanks in series and adding small quantities of some precipitant to the liquid as it passed into the second tank.

21992. 45. Colonel T. W. Harding and Mr. W. H. Harrison carried out a series of experiments at Leeds, in which flows sufficient to fill the septic tanks in 12, 24, 48, and 72 hours were compared. The results showed that at that place, and using simple rectangular tanks, a rate of flow sufficient to fill the tank once in 24 hours was the best economic rate. Rates of flow slower than this gave only slightly better results as regards suspended matter in the tank liquor, and greater rates of flow brought out more suspended matter than it was thought desirable to send on to the filters. The experiments showed also that, if the flow was increased to a rate which filled the tank in 12 hours, the tank

* As to "stand-by" tanks see section dealing with treatment of storm water sewage, p. 204.

became choked with sludge before septic action was induced. The figures of analysis for the different rates of flow are given in the Report on Experiments in Sewage Disposal, City of Leeds, June, 1905, p. 66, as follows :—

Average Analyses referring to the effect of different rates of flow through open Septic Tanks.

Grains per gallon.	12 hours' flow.		24 hours' flow.		48 hours' flow.		72 hours' flow.*	
	Average analysis.	Per-centage reduction on crude sewage.	Average analysis.	Per-centage reduction on crude sewage.	Average analysis.	Per-centage reduction on crude sewage.	Average analysis.	Per-centage reduction on crude sewage.
Total solids - - - -	87·7	—	78·2	—	78·3	—	73·9	—
Suspended Solids - - -	19·2	52	11·4	71	10·9	73	9·9	76
Free Ammonia - - -	1·56	22	1·51	24	1·62	19	1·79	37

Oxygen absorbed in 4 hours at 80° F.	5·21	45	4·84	49	4·30	55	3·59	55

* Experiment at later date with weaker sewage.

46. Dr. G. J. Fowler, in his evidence relating to Manchester (May 12th, 1905 ; answer to Question 22773), says :—

"The most advantageous rate of flow is largely a matter of circumstances. It may be roughly taken from available experience that, with sewage of a strength of 40 gallons per head, about 24 hours' flow is desirable ; with a greater flow per head (the organic matter remaining the same) the rate may be correspondingly quicker and, with a less flow, less. Our knowledge on this subject is very imperfect. One may say, at any rate, that time must be given for settlement of the grosser solids and hydrolysis of the lighter suspended matter. Much, of course, depends on the length of travel in the sewer ; with a long travel the simple hydrolytic changes will already be almost complete, whereas, on the other hand, in latrine sewage the matter entering the tank may be practically in its original condition. There can be little doubt that the chief activity of the septic tank resides in the sludge and this needs to remain in the tank a very long time for thorough digestion to take place."

In answer to a further question (22979), Dr. Fowler stated that 24 hours' stay in the tank is the longest time he would allow.

Messrs. Watson and O'Shaughnessy, in their evidence relating to Birmingham (May 18th, 1905 ; answer to Question 24983), say :—

"The actual mean rate of flow through the first set of tanks is ·87 feet per minute, and through the second set of tanks ·32 feet per minute. This rate of flow is sufficient to set up most vigorous fermentation, and results in the destruction of very considerable quantities of organic matter, as evidenced by the copious evolution of gas from the tanks, and by the increase in the amount of 'free ammonia' in the tank liquor. A quicker rate of flow is detrimental to the septic action. The action is continued in the large conduit, the liquor taking something like 6 hours to traverse it. At the end of the conduit is a Dortmund tank installation, and here we have been able to make some interesting observations on the behaviour of this already highly septic liquor. We consider that septic treatment of Birmingham sewage for a period of at least 24 hours to be distinctly advantageous. At the present time this is as much as we can say definitely. The observed effect of additional septic treatment at the end of the conduit, in the Dortmund tank, is a great increase in the number of micro-organisms in the tank liquor. We consider that the rate of flow should depend very largely on the strength and on the character of the particular sewage to be dealt with—a stronger sewage requiring a longer time, and certain constituents of sewage being more easily broken down than others."

47. As regards the question whether it is possible to "over septicise" a sewage, several witnesses have stated that if sewage be kept too long in the tank, the amount of sulphuretted hydrogen produced is considerably increased, and some witnesses have expressed the view that too long a stay tends to impair the subsequent oxidation of the sewage during its passage through the filters.

Should Septic Tanks be closed or open?

48. We are not aware that any comparative observations have been made of the relative merits of closed and open tanks in the case of a domestic sewage, but comparative experiments have been carried out at Birmingham, Burnley, Leeds, and Manchester, which show that, as regards digestion of sludge and quality of tank liquor, the closed tank possesses no advantages over the open tank.

49. In cases, however, where it is important to avoid nuisance from smell, our experience shows that the closed tank is generally preferable.

At Exeter, Yeovil, Andover, Hartley Wintney, and Prestolee, where the tanks are covered in, the smell from the tanks themselves is almost entirely done away with.

At Accrington, Leeds, Rochdale, and Burnley, where the tanks are uncovered, there is, as a rule, appreciable local smell.

At Sheffield, the nuisance arising from the open (experimental) septic tank was so pronounced, that the men on the works raised strong objections.

At Gosport, a very serious nuisance arose from open septic tanks, which was almost entirely done away with by completely roofing over the whole of the tanks and channels at the works.

At Guildford and Carshalton it was found necessary to put a rough covering over the tanks. In both cases the smell was largely diminished as the result.

At Ilford, a substantial roof is now being provided, to diminish the smell.

On the other hand, at Birmingham and Manchester, very little smell arises from the open septic tanks. This is no doubt accounted for by the fact that the sewages contain manufacturing waste, iron salts in the case of Birmingham, and iron salts and tarry matter in the case of Manchester.

50. As regards closed tanks, we may observe that a roof somewhat hampers sludging operations, and further, that care is necessary to avoid explosion of the gas which accumulates under the roof. Serious accidents have been caused by the explosion of the gas in closed septic tanks.

Arrangements for removing Suspended Solids from Septic Tank Liquor before it is delivered to the Filters.

51. So far as we know, none of the attempts to screen septic tank liquor by passing it through a short depth of material have been successful. At Leeds a layer of fairly fine material was suspended in a small septic tank in such a way as to cause the liquor to pass through it before leaving the tank. The sludge lying at the bottom of the tank, in rising to the surface as a result of the evolution of gas completely clogged the bottom of this material and rendered it worse than useless for screening purposes.

At Ilford and Guildford layers of coarse material have been placed at the outlet sills of the tanks, but it appeared to us that this arrangement was ineffective.

At Chester a plan similar to that tried at Leeds was followed, but after a short time the straining material became seriously choked with the suspended matter rising from the bottom of the tank. The tank liquor consequently forcing its way to the surface through special channels, bringing a great deal of suspended matter with it.

52. At Salford, *precipitation liquor* is forced by head of water (5′ 6″) through a layer of medium to coarse gravel (½ to 1½ inches diameter), three feet in depth, laid at the bottom of some specially constructed tanks, called "Roughing filters." This plan undoubtedly removes a very considerable quantity of the suspended matter from the precipitation liquor. The area of these "Roughing filters" is, however, so small compared to the volume of precipitation liquor to be passed through them, that they can only deal with two-thirds of the flow, the gravel being almost always more or less clogged. About 8,000,000 gallons of precipitation liquor are, on the average, forced through the "Roughing filters" per day, and as the total area of filtering material in the tanks is only 2,040 square yards, the average rate of filtration is roughly 4,000 gallons per square or per cube yard per day. The material in the "Roughing filters" at Salford is washed by upward flow once in every six days, each filter working for five days and resting for one. Once a year the gravel is taken out and thoroughly washed. The average analysis of the Salford precipitation liquor, after it had passed through the roughing filters, is given by Mr. J. Carter Bell, as follows :— Bell, 23207.

1903 and 1904.

	Parts per 100,000.
Oxygen absorbed from permanganate in four hours	4·7
Alkalinity as calcium oxide	3·0
Free and saline Ammonia	1·95
Albuminoid Ammonia	·45
Nitrogen as Nitrates and Nitrites	·172
Chlorine	14·1
Suspended solids	2·9

Mr. Carter Bell stated that it has been found practicable at Salford to remove about 75 per cent. of the suspended matter of the precipitation liquor by means of the roughing filters. 23225

53. At Friern Barnet the precipitated sewage is given a two hours' contact in contact beds, called roughing filters, before it passes to the low level percolating filters. These roughing filters consist of medium-sized clinkers, four feet nine inches in depth. They remove a considerable portion of the suspended matter from the precipitation liquor, and may be looked upon as primary contact beds.

Straining tanks of a somewhat similar kind have been in use at Wimbledon for a number of years. In these, however, the filtering material (three feet in depth) rests on a false bottom, some distance from the bottom of the tank, and the sewage entering at the bottom of the tank flows upward through the material, a large portion of the suspended matter settling upon the floor of the tank underneath the material. The tanks are cleaned at short intervals of time. We believe the plan has been found to work well.

54. At Birmingham Mr. J. D. Watson interposes modified Dortmund tanks between the septic tanks and the continuous filters. He states that the average of nearly a year's observations shows that the Dortmund tanks removed 75 per cent. of the suspended matter from the Birmingham septic tank liquor. It must be remembered, however, in regard to this, that the Birmingham septic tank liquor contained a large quantity of suspended matter, the average amount for the year 1904 being 19·5 parts per 100,000. If Dortmund tanks were used for the settlement of tank liquors containing only small quantities of suspended matter (say five parts per 100,000), they would, we think, probably not be as efficient as some straining method such as that adopted at Salford. Watson, 25001.

55. A special tank has been designed by Dr. Owen Travis for the further removal of suspended and colloidal matter from the septic tank liquor at Hampton. We have not, ourselves, been able to make any observations on this tank.

Lime Precipitation following Septic Tank Treatment.

56. From some experiments which we have carried out at Dorking, we find that, by passing septic tank liquor through tanks of a size sufficient to hold about one quarter of the 24 hours flow, with the addition of from 2 to 3 grains of lime per gallon

to the liquor, the suspended solids are reduced from 8 to 5 parts per 100,000, a considerably larger quantity of the liquor can be purified per cube yard of filter, and the offensive character of the septic tank liquor is largely destroyed. The solids which are chiefly reduced are those which are volatile.

In many cases we think that this combination of septic tank treatment and precipitation will be found to be useful.

We have, however, had no experience of this arrangement on a large scale.

A small quantity of lime (about 1 grain per gallon) has been added to the septic tank liquor at Blackburn for some years with a view to aiding subsequent nitrification on the filters.

Chemical Precipitation.

57. There has been a tendency on the part of certain authorities to regard the chemical precipitation of sewage as an obsolete form of preliminary treatment. Our experience in no way justifies this view, and while we are not able to lay down any precise rules as to the particular cases in which chemical precipitation should be adopted, nor as to the relative cost and efficiency of the various precipitants which are available, we think it may be useful to state generally the results of our observations.

In the case of some sewages, which contain trade waste, it is almost essential to subject the sewage to some form of chemical treatment before attempting to oxidise the organic matter contained in it, and in the case of domestic sewages, chemical precipitation materially aids the deposition of the suspended solids, and facilitates subsequent filtration.

58. The actual amount of suspended solids remaining in the sewage after chemical precipitation varies according to a number of factors, but in the case of a domestic sewage, which is allowed to stand and settle for about 2 hours, it is practicable to produce a tank liquor containing from 1 to 4 parts per 100,000. Where the settlement is effected by continuous flow through the tank, at an 8-hour rate, the suspended solids may be brought down to from 3 to 6 parts per 100,000.

59. Excepting for the results relating to the Dorking sewage, which are given below, we have ourselves made no comparative experiments with regard to the relative cost and efficiency of the various substances used for the precipitation of sewage. We have, however, had some experience of the following precipitants, at works which have been under our observation :—

Lime.
Lime used in conjunction with Copperas (Ferrous Sulphate).
Lime used in conjunction with Alumino-ferric.
Alumino-ferric.
Alumino-ferric used in conjunction with blood, charcoal and clay (A.B.C. process).
Ferrozone.
Ferric Sulphate.
Sulphuric Acid.

At most of the works where domestic sewage has been treated, alumino-ferric has been the precipitant used. At some of the works, this precipitant has displaced ferrozone on the score of economy, and at Chorley, a considerable saving in cost (about £1 per million gallons) was effected by the manufacture of alumino-ferric upon the works.

At Dorking, although we did not experiment with equal aggregate quantities, the results of a series of experiments led us to the conclusion that a better result was obtained from a mixture of lime and alumino-ferric than from alumino-ferric alone.

The same conclusion, we believe, resulted from experiments made by Mr. Creer, the City Engineer of York, with the sewage of that city. Owing to its low solubility in water, lime requires automatic machinery for crushing and mixing before it can be effectively added to the sewage, and for very small sewage works its use would not be economical.

60. The following table gives a list of places where domestic sewage alone, or mixed with small quantities of trade refuse (as a rule brewery or tannery waste), is precipitated, the quantity of precipitant used, the dry weather flow of sewage, and the cost of the precipitant :—

TABLE I.

Place.	Precipitant.	Quantity of precipitant added (in grains per gallon). Based on the dry-weather flow.	Dry weather flow of sewage (treated by the precipitation process).	Character of Sewage.	Cost of precipitant per million gallons. Based on dry-weather flow.	Cost of precipitant per million gallons. Based on average daily flow.	Year.
Withnell -	Alumino-ferric -	15·7	*Gallons.* 10,000	Very strong	£ s. d. 5 6 0	£ s. d.	1903.
Radcliffe -	Alumino-ferric -	8·0	800,000			2 15 0	1902, 1903, 1904 & 1905.
Calverley	Alumino-ferric -	17·5	12,000	Very strong	2 10 0		1904.
Heywood -	Alumino-ferric -	8·0	630,000	Average strength.		1 7 6	
	Ferrozone - -	8·0	630,000			1 6 6	
Guildford -	Alumino ferric -	8·0	300,000	Very strong	2 2 0	1 4 5	1905.
Horfield -	Alumino-ferric -	5·0	40,000	Average strength.	1 10 0	0 17 6	1905.
Normanton -	Alumino-ferric -	6·7	175,000	Very strong	1 5 0		1902 to 1905.
Hendon -	Alumino-ferric -	5·5	950,000	Rather strong.		0 13 3	1906.
Chorley -	Alumino-ferric -	9·0	900,000	Average strength.		0 12 10	1902.
Royton -	Alumino-ferric -	2·22	367,500			0 6 7½	1906.
Buxton	Natural Iron-water - -	6–7 } 12 to 13	750,000			0 4 6	1906.
	Milk of Lime -	6 }					
Dorking -	Lime - -	5·6 } 9·1	200,000	Average strength.		0 15 8	1902, 1903 & 1904.
	Alumino-ferric -	3·5 }					
Friern Barnet	Lime - -	4·0 } 6·0	350,000		Lime 5/1 Alumino-ferric 7/7½ }	0 12 8½	
	Alumino-ferric -	2·0 }					
York - -	Lime - -	5·77 } 10·0	3,750,000	Average strength, or perhaps under average.		0 10 7	1904–1905.
	Alumino-ferric -	4·3 }					
Willesden -	Lime - -	3·85 } 9·31	1,930,950		Lime 1/5·38 Alumino-ferric 8/6·5 }	0 10 0	
	Alumino-ferric -	5·46 }					
Ealing -	Lime - -	4·0 } 6·0	1,000,000			0 6 9	Three years ending March, 1906.
	Alumino-ferric -	2·0 }					
Leyton -	Lime - -	15·0 } 22·0	3,000,000			3 11 0	1905–1906.
	Hanson's Sulphurous Powder - -	7·0 }					
Kingston -	Alumino-ferric, blood, charcoal, and clay (A.B.C. process) - - -	50·0	2,750,000	Average strength.		3 4 0	1902, 1903 & 1904.
Rochdale -	Alumino-ferric -	7·3 } 12·0	2,000,000	Very strong		1 8 7	1904–1905.
	Sulphuric Acid -	4·7 }					

NOTE.—It will be observed in the above table that at nearly all the places where lime is used as a precipitant the cost is relatively low. In regard to this, however, it must be stated that the figures of cost refer to the lime alone and do not include any charges with respect to the mixing. This might add, we think, from 2/– to 10/– per million gallons, according to circumstances.

61. In Table II. some of the places where we have made special observations are arranged in the order of percentage reduction in suspended matters. The figures for Withnell and Calverley are not included, the flow of sewage at those places being too small for proper comparison with the others.

TABLE II.

Place.	Precipitant.	Percentage reduction of suspended matter in the crude sewage.	Amount of precipitant added in grains per gallon. Based on dry-weather flow.	Actual amount of suspended matter left in the precipitation liquor (parts per 100,000).	Cost of precipitant alone per million gallons, based on the average daily flow.	Strength of precipitation liquor calculated on the basis suggested by Dr. McGowan, *see* p. 16.	Strength of crude sewage calculated in a similar manner.
					£ *s.* *d.*		
Kingston -	Alumino-ferric, blood, charcoal, and clay (A.B.C. process)	95	50·0	1·5	3 4 0	51	94
Horfield - -	Alumino-ferric	93	5·0	2·5	17 6 (approx.)	36	88
Chorley - -	Alumino-ferric	91	9·0	2·9	1 0 2*	50	106
Heywood -	Alumino-ferric	82	8·0	5·0	1 7 6	42 (approx.)	
Dorking - -	Lime -	82	9·0	7·0	15 8 (approx.)	about 60	95
Hendon - -	Alumino-ferric	80	5·5	5·5	13 3	58	110
Rochdale - -	Alumino-ferric and sulphuric acid	79	12·0	7·8	1 8 7	77	203
Guildford -	Alumino-ferric	75	6·5	14·6	1 4 5	171	194
Normanton -	Alumino-ferric	67	6·7	18·0	1 5 0	112	235
York - -	Lime and alumino-ferric	64	10·0	7·7	10 6	63	115

62. In comparing the costs in Table II., the influence which the suspended matter left in the liquor has upon the life of the filter-beds, used subsequently, must be specially borne in mind. For instance, according to their calculated strengths, the Kingston and Chorley precipitation liquors would require about equal filter areas, but the Kingston liquor only contains 1·5 parts per 100,000 of suspended solids against 2·9 parts in the Chorley liquor, and on the assumption that the rate of clogging is broadly in proportion to the amount of suspended matter in the liquor treated, if the two liquids were treated upon equal areas of *contact* beds, the filtering material would require washing twice as often at Chorley as at Kingston. The amount of colloidal matter is not great in either liquor.

The A.B.C. process is, undoubtedly, a very efficient form of chemical precipitation, and the dried sludge produced at Kingston is sold by the company.

In regard to all tank processes, it may be remarked that the greater the amount of suspended matter in the original sewage, the easier it is to obtain a good *percentage* reduction of the suspended solids.

* This figure applies to the year 1900, when the alumino-ferric was bought. At the present time (1906), when the alumino-ferric is made on the works, the cost of precipitation per million gallons is 12*s.* 10*d.*

63. In the experiments carried out under the Massachusetts State Board of Health, Mr. Allan Hazen compared lime, lime and ferrous sulphate, ferric sulphate and aluminum sulphate as used in various quantities upon the St. Lawrence sewage during the year 1889 (Report of experiments upon the chemical precipitation of sewage. State Board of Health, Massachusetts, 1890). The sewage was a very weak one.

The following are quotations from the summaries given in the Report by Mr. Hazen on these experiments:—

The Comparative Advantages of the Different Precipitants.

"It does not seem to me that the slight colour given by the use of iron "should be considered an objection in judging the merits of the different "processes. It should be remembered that when alum is used, a small "portion of the alumina is really present in the effluent, but being white, it "is not noticed as is a corresponding amount of iron.

"The lime process has little to recommend it. Owing to the large amount "of lime-water required and the difficulty of accurately adjusting the lime to "the sewage, very close supervision would be required to obtain a good "result, and, even then, the result is inferior to that obtained in other "ways.

"Precipitation by copperas is also somewhat complicated, owing to "the necessity of getting the right amount of lime mixed with the sewage "before adding the copperas. When this is done, a good result is obtained. "The amount of iron left in the effluent is much greater than the ferric "sulphate owing to the great solubility of ferrous hydroxide.

"Ferric sulphate and alum have the advantage over both lime and "copperas, that their addition in concentrated solution can be accurately "controlled, and the success of the operation does not depend upon the "accurate adjustment of lime or any chemical to the sewage. The results "with ferric sulphate have been, on the whole, more satisfactory than those "with alum. This seems to be due in part to the greater rapidity with "which precipitation takes place and in part to the greater weight of the "precipitate. It is probable, from the greater ease with which ferric "sulphate is precipitated, that it would give a good result, with a sewage "that was not sufficiently alkaline, to precipitate alum at once. It is quite "possible that the same process would not give equally good results upon "all kinds of sewage. Special sewages may require special treatment. "For this reason, and also on account of changes in the prices of the several "chemicals, it is impossible to say that one precipitant is universally better "than another."

Conclusions.

"Using equal values [*i.e.*, as regards price] of the different precipitants, "applied under the most favourable conditions for each, upon the same "sewage, the best results were obtained with ferric sulphate. Nearly as "good results were obtained with copperas and lime used together, while "lime and alum each gave somewhat inferior effluents. The range of these "results was, however, comparatively narrow; and it may be that with a "sewage of a different character, or with variations in the prices of the "chemicals, it would be advantageous to use copperas with lime, or even "alum. When lime is used, there is always so much lime left in solution "that it is doubtful if its use would ever be found satisfactory except in "case of acid sewage."

64. Various comparative experiments with precipitants have been made at a number of large towns and cities in this country; for instance, at Glasgow, amongst other experiments of the same kind, Mr. Thomas Melvin has experimented with sulphate of alumina and ferric sulphate, both used in conjunction with lime. The sulphate of alumina (44·5% $Al_2(SO4)_3$), which was bought, cost 33s. per ton, while the ferric sulphate (9% Fe), made upon the works, cost 11s. 3d. per ton. In each of the trials (which extended over long periods) 8 grains per gallon of the precipitant were used in conjunction with 4 grains per gallon of lime. We understand that ferric sulphate and lime always gave the better result.

Sir Thomas Wardle ("Sewage Treatment and Disposal") also obtained good precipitation results by the use of a mixture containing basic ferric sulphate as its chief ingredient.

Fowler, 22758. In his evidence relating to Manchester Dr. G. J. Fowler stated:—

"I have had experience with various chemicals, viz., lime and copperas, "ferric salts and alumino-ferric, but have not gone very exhaustively into "their various merits. Lime and copperas give a precipitate which readily "settles, and lime is useful where flushes of acid have to be neutralised. On "the other hand, their use requires constant and skilled supervision, and "is therefore less suitable for small works than alumino-ferric, where a given "quantity can be added from time to time and be left to dissolve in the "incoming sewage. Ferric salts I have not found to give so rapid pre-"cipitation as either the lime and copperas or the alumino-ferric. The "precipitate appears more finely divided than either of the others. More-"over, ferric salts, unless made on the works, are not readily obtained in "the quickly soluble and, at the same time, transportable condition. The "following are prices per ton delivered at or near Davyhulme, showing that "for equal weights, lime and copperas are undoubtedly cheaper than "alumino-ferric:—

"Lime	11s. 6d.
"Copperas	21s. 6d.
"Alumino-ferric	40s. 0d.
"Ferric sulphate	23s. 6d.

"These prices will, of course, vary in different parts of the country."

Watson 24968. Mr. J. D. Watson and Mr. F. R. O'Shaughnessy, in their evidence relating to Birmingham, stated:—

"Milk of lime added to the crude sewage was used as a chemical "precipitant for many years, and was totally discontinued in February, 1901. "During the last twelve months of this process the tank capacity at the out-"fall works consisted of two installations of tanks, which were worked in "series. The mean period of sedimentation in the preliminary tanks was "3½ hours, and in the secondary installation of tanks the mean period of "sedimentation amounted to 5½ hours, giving a total mean period of "sedimentation for the limed crude sewage of 9 hours. The flow of sewage "for the last twelve months of the process was estimated at twenty million "gallons per day. The proportion of lime added to the crude sewage was "12 grains per gallon, being the equivalent to a quantity of 15 tons 6 cwts. "dry lime used daily.

"The following analysis will indicate the effect of this liming process "upon the crude sewage:—

Year 1900.	Parts per 100,000.	
	Dissolved Solids.	Suspended Solids.
Crude Sewage	129·1	67·6
Preliminary Tank Liquor	138	16·3
Final Tank Liquor	133·2	4·2*

Harrison, 21979. Mr. Harrison, in his evidence relating to Leeds, stated:—

"Several precipitants have been tried upon the Leeds sewage in order "to obtain their relative values, but the question of cost has not been

* It must be borne in mind that the Birmingham sewage contains iron salts in considerable quantity, so these good results cannot be ascribed to the lime alone.

"considered. The most effective precipitant was a mixture of ferric salt and "lime, closely followed in merit by aluminum sulphate and lime. These two "precipitants were almost equally effective, and were followed in order of "merit by alum and lime, ferrous sulphate and lime, ferric salts, alum and "ferrous sulphate. The last was practically valueless."

Mr. Carter Bell in his evidence relating to Salford, stated:— Bell, 23218.

"We have tried many systems of sewage purification and combinations "of chemicals. The best and most economical results have been obtained by "the use of lime followed by salts of iron."

Mr. Bolton, in his evidence relating to Heywood, stated:— Bolton, 21107.

"I have tried various chemicals. Iron and alumina compounds have "been used under such trade names as alumite, kremnolite, ferrozone, "alumino-ferric, etc. Alumino-ferric is the best precipitant tried at "Heywood. With an addition of 8 grains per gallon, a purification of "62 per cent. is brought about. This equals £1 7s. 6d. per million gallons. "Ferrozone under the same conditions brought about a purification of 57 "per cent., equal to a cost of £1 6s. 6d. per million gallons. Thus, for 3·6 "per cent. reduction in price 8 per cent. less purification was obtained "by ferrozone."

65. Where the sewage, by reason of the discharge of large quantities of trade refuse, is of a special character, special precipitants have, of course, to be used.

At Bradford, where there is a very large proportion of wool-scouring refuse in the sewage, sulphuric acid is used as the precipitant, in order to separate the fat, which is afterwards extracted from the sludge.

At Rochdale, where on several days of the week, owing to the discharge of wool-scouring refuse, the sewage resembles that of Bradford, sulphuric acid is used to neutralise the alkali in the wool-scouring refuse *after* the precipitation of the sewage with alumino-ferric.

At Burton-on-Trent, where there is a largely preponderating quantity of brewery waste in the sewage, very large quantities of lime have to be added.

Ways of adding chemicals.

66. Chemicals are most effective in precipitating a sewage when they are added in the form of a solution.

In practice, however, the addition of a solution of precipitant to a sewage is not always so economical or effective as the use of the precipitant in a solid form, owing to the fact that it is advisable to vary the quantity of the solution with the varying strength of the incoming sewage—a matter of some difficulty at a small works.

At a large works, where the addition of the chemicals can be properly supervised, we should think that, with the exception of lime, all chemicals should be added in the form of a solution. Lime is best added in the form of milk of lime, as it is not very soluble in water, and its addition in solution, involves the use of large quantities of water or sewage.

At medium-sized or small works it is usually found best, for economy of labour, to add such precipitants as alumino-ferric or ferrozone in the form of a solid block, placing the block in the sewage channel so that the top of it projects above the level of the sewage. In this way the largest quantities of precipitant are dissolved at those times of the day when the flow of sewage is greatest.

67. At Horfield and Hendon we found a simple and effective way of adding alumino-ferric in the form of a solution. The quantity of precipitant required for about 24 hours was, each morning, put into a box with a false bottom, and the alumino-ferric was dissolved by allowing water to drip on to it. During the daytime, when the box was full of precipitant, and when the sewage was strongest, a larger amount of the alumino-ferric was delivered to the sewage, owing to the solution being then stronger than it was at night, when almost all the precipitant had dissolved away. Moreover, the dose could be varied at will by increasing the flow of water.

This plan appeared to us to be rather more effective than the method of placing blocks of the precipitant in the sewage channels, though that method is also in the main satisfactory.

We have had no experience of copperas used alone; in the cases that have been brought to our notice, it has been used along with milk of lime. In these cases it has usually been found best to add it after the lime.

Immediately after the addition of any chemicals the sewage should be churned up so as to produce a thorough mixture. This can be done effectively by some mechanical apparatus or by baffling boards.

Some Observations as to the Relative Cost of various Preliminary Processes.

68. Local conditions and circumstances must always be the first consideration in the selection of a process for the preliminary settlement of the sewage of any particular place, and it is not possible to give figures of cost which would apply generally.

We think, however, it will be useful to compare the various processes in common use in a hypothetical case in which we assume :—

That ample fall is available;
That the sewage is of a normal domestic character and of average strength;
That the flow of sewage is 1,000,000 gallons per day in dry weather;
That all tanks are of simple construction, and rectangular in shape.

The processes which we propose to compare are :—

Septic tanks;
Continuous flow settlement without chemicals;
Quiescent settlement without chemicals;
Continuous flow settlement with chemicals;
Quiescent settlement with chemicals.

Comparative Capacities of Tanks.

69. From our general experience and from a consideration of the evidence we think the various lengths of time required for settlement and the number of tanks may, for the purpose of this comparison, be those shewn in the following table:—

Preliminary Process (arranged in order of tank capacity).	Stay in Tanks.	Total Number of Tanks.	Number of Spare Tanks.	*Total Capacity of Tanks required (gallons).
Continuous flow settlement with chemicals	8 hours	8	2	444,440
Continuous flow settlement without chemicals	15 hours	8	2	833,333
Quiescent settlement with chemicals	2 hours	10	2	1,041,660
Quiescent settlement without chemicals	2 hours	10	2	1,041,660
Septic tanks	24 hours	6	1	1,200,000

* The tanks would be sufficiently large to deal with 3,000,000 gallons per day in times of storm.

Initial Cost of Tanks.

70. From these estimates of the total tank capacities, Mr. G. B. Kershaw, our Engineer, has prepared drawings for each preliminary process, from which he has taken out complete quantities, and prepared the following estimates :—

Preliminary Process (arranged in order of cost).	Constructional Cost of Tanks.
Continuous flow settlement with chemicals	£3,797
Continuous flow settlement without chemicals	£5,112
Quiescent settlement with chemical	£5,987
Quiescent settlement without chemicals	£5,987
Septic tanks (open)	£6,891

Cost of Chemicals.

71. Several different substances are used in practice for the precipitation of sewage, dependent to some extent on the kind of sewage to be dealt with. For the precipitation of domestic sewage of about average strength, however, alumino-ferric is by far the most common and we have adopted this precipitant in our hypothetical case. The average quantity of the precipitant used may be put at about 10 grains per gallon (or 14·3 parts per 100,000). The cost of alumino-ferric varies at different places; but taking it at £2 5s. per ton, the cost of chemicals work out at £523 15s. per year or £1 8s. 8d. per million gallons of sewage (dry weather flow).

Production of Sludge.

72. We think it may be taken that, on the average, domestic sewage contains about 35 parts of suspended matter per 100,000 in dry weather, and that 1,000,000 gallons of domestic sewage would, in dry weather, produce approximately 1 ton 11 cwt. of *dry* sludge, *i.e.*, sludge containing no moisture. Where the quantity of alumino-ferric added is not excessive, practically the whole of its alumina is thrown out of solution, and since there is considerable evidence to show that small quantities of dissolved or colloidal sewage matter are also precipitated, we may assume for the purposes of this argument that, in addition to the 35 parts of suspended matter in the sewage, something like 5 parts of additional solid matter* must be taken into account. We assume, therefore, that our hypothetical sewage, with its precipitant, contains $35+5=40$ parts per 100,000 of suspended matter as it enters the tanks. From this must be deducted the amount of suspended matter issuing in the tank liquor, and, from a large general experience, we estimate that the addition of 10 grains per gallon of alumino-ferric to our hypothetical sewage would produce a tank liquor containing on the average about 2·5 parts per 100,000 of suspended matter if quiescent settlement were adopted, and about 4·5 parts per 100,000 if continuous flow settlement were adopted. On this basis the dry solid matter left in the settling tanks as the result of these two preliminary processes would be as follows :—

	Parts per 100,000.
Chemical precipitation followed by quiescent settlement	$35+5-2\cdot5=37\cdot5$
Chemical precipitation followed by continuous flow settlement	$35+5-4\cdot5=35\cdot5$

73. With settlement of sewage without chemicals, we estimate that the quantity of suspended matter issuing in the tank liquor would be approximately 7 parts per 100,000 after quiescent settlement, and 10 parts per 100,000 after continuous flow settlement. The dry solid matter left in the tanks, therefore, would be :—

	Parts per 100,000.
Quiescent settlement, without chemicals	$35-7=28$
Continuous flow settlement, without chemicals	$35-10=25$

* Alumino-ferric contains roughly 50 per cent. by weight of $Al_2(SO_4)_3$. If the whole of the alumina were precipitated by the sewage 14·3 parts per 100,000 of alumino-ferric would thus give approximately 2 parts per 100,000 of dry Al_2O_3. To the alumina must be added the colloidal matter thrown down by the action of the alumino-ferric upon the sewage, and we have estimated this at approximately 3 parts per 100,000. The latter figure has, however, been obtained from a comparatively small number of analyses.

74. In the case of septic tanks the digestion of sludge must be taken into account, as well as the amount of suspended matter carried away in the tank liquor. The digestion of sludge from a domestic sewage may be put approximately at 30 per cent. of the total suspended matter entering the septic tank, and on the average the liquor issuing from the septic tank would contain 10 parts of suspended matter. On this basis, the amount of sludge left in the septic tank would be $35 - 10 - 10 \cdot 5 = 14 \cdot 5$ parts per 100,000.

75. The production of sludge in our five preliminary processes of settlement would, therefore, be represented by the following figures :—

Preliminary Process.	Sludge left in Tanks (in parts per 100,000).
Quiescent settlement with chemicals	37·5
Continuous flow settlement with chemicals	35·5
Quiescent settlement without chemicals	28·0
Continuous flow settlement without chemicals	25·0
Septic tanks	14·5

Taking the average percentage of water in the sludges generally at 90, we obtain the following figures for the production of wet sludge by each preliminary process per 1,000,000 gallons :—

Preliminary Process.	Wet sludge (90 per cent. water) produced per million gallons of sewage (dry weather flow).
Quiescent settlement with chemicals	17 tons
Continuous flow settlement with chemicals	16 „
Quiescent settlement without chemicals	12 „
Continuous flow settlement without chemicals	11 „
Septic tanks	6·5 „

Cost of Labour.

(*a*) Disposal of Sludge.

76. The various methods of disposing of sludge are not in every case suited to each kind of sludge. Septic tank sludge, for instance, is rather difficult to press, being usually greasy. For the purposes of comparison we have selected the plan of shallow burial in the soil, as this method is for practical purposes equally well suited for the disposal of the sludge from each preliminary process.

For the burial of 1,000 tons a year of wet sludge (90 per cent. water), we estimate that one acre of land with soil of good or medium quality is necessary. On this basis the following areas would be required for the burial of the sludge from the various preliminary processes :—

Preliminary Process.	Quantity of wet sludge (90 per cent. water) produced per annum.	Area of Land required.
Quiescent settlement with chemicals	6,205 tons	6·20 acres
Continuous flow settlement with chemicals	5,840 „	5·84 „
Quiescent settlement without chemicals	4,380 „	4·38 „
Continuous flow settlement without chemicals	4,015 „	4·01 „
Septic tanks	2,372 „	2·37 „

The trenching of this land and the covering of the sludge would probably require the whole time of two men in the case of the two chemical precipitation processes and the quiescent settlement process, and one man in the case of the continuous flow settlement process.

In the case of the septic tank process additional labour would only be required when the tanks came to be cleaned out, say, twice a year. On the assumption that the services of some six men would be required for a fortnight on these occasions, we estimate that this would involve a labour expenditure of about £30 per annum.

Taking labourer's time at 21s. a week, and including one-third of the manager's time at a salary of £130 per annum, the labour cost in connection with the sludge trenching would be as follows :—

Preliminary Process.	Cost of labour and Supervision in connection with the Disposal of Sludge on the Land.	
	Per annum.	Per million gallons of sewage (dry weather flow).
	£	s. d.
Quiescent settlement with chemicals	152	8 4
Continuous flow settlement with chemicals	152	8 4
Quiescent settlement without chemicals	152	8 4
Continuous flow settlement without chemicals	98	5 4
Septic tanks	73	4 0

(*b*) Working and Sludging of Tanks.

77. For the working and sludging of the tanks we estimate that the services of three men would be required in the case of the two chemical precipitation processes and in that of quiescent settlement, and of two men in the case of the continuous flow settlement process and the septic tank process.

Taking labourers' time at 21s. a week, and including one-third of the manager's time, at the salary of £130 per annum, we obtain the following figures :—

Preliminary Process.	Labour and Supervision in connection with Tanks.	
	Per annum.	Per million gallons of sewage (dry weather flow).
	£	s. d.
Quiescent settlement with chemicals	208	11 5
Continuous flow settlement with chemicals	208	11 5
Quiescent settlement without chemicals	208	11 5
Continuous flow settlement without chemicals	152	8 4
Septic tanks	152	8 4

Loan Charges.

78. Taking the price of land at £100 per acre, and assuming that the loan is raised at $3\frac{1}{2}$ per cent interest per annum and is repayable in equal annual instalments in thirty years, the annual loan charges in respect of the initial cost of tanks and of the land on

which the tanks are constructed and in which the sludge is buried would be as shown in the following table:—

Preliminary Process.	Loan Charges.	
	Per annum.	Per million gallons of sewage (dry weather flow).
	£ s. d.	£ s. d.
Quiescent settlement with chemicals	374 5 9	1 0 6
Continuous flow settlement with chemicals	251 4 11	0 13 9
Quiescent settlement without chemicals	364 7 9	0 19 11
Continuous flow settlement without chemicals	314 12 8	0 17 3
Septic tanks	404 4 11	1 2 2

Total Cost of the Preliminary Processes.

79. Arranged in the order of their total annual cost, including repayment of principal and interest on loans, the five processes are as follows:—

	£ s. d.
Continuous flow settlement without chemicals	564 12 8
Septic tanks (open tanks)	629 4 11
Quiescent settlement without chemicals	724 7 9
Continuous flow settlement with chemicals	1,134 19 11
Quiescent settlement with chemicals	1,258 0 9

The details are:—

Per Annum.

Preliminary Process.	Chemicals.	Labour and Supervision.	Loan Charges.	Total.
	£ s. d.	£	£ s. d.	£ s. d.
Quiescent settlement with chemicals.	523 15 0	360	374 5 9	1,258 0 9
Continuous flow settlement with chemicals.	523 15 0	360	251 4 11	1,134 19 11
Quiescent settlement without chemicals.	—	360	364 7 9	724 7 9
Continuous flow settlement without chemicals.	—	250	314 12 8	564 12 8
Septic tanks	—	225	404 4 11	629 4 11

Per Million Gallons of Sewage (dry weather flow).

Preliminary Process.	Chemicals.	Labour and Supervision.	Loan Charges.	Total
	£ s. d.	s. d.	£ s. d.	£ s. d.
Quiescent settlement with chemicals.	1 8 8	19 9	1 0 6	3 8 11
Continuous flow settlement with chemicals.	1 8 8	19 9	0 13 9	3 2 2
Quiescent settlement without chemicals.	—	19 9	0 19 11	1 19 8
Continuous flow settlement without chemicals.	—	13 8	0 17 3	1 10 11
Septic tanks	—	12 4	1 2 2	1 14 6

In so far, therefore, as the preliminary tank process by itself is concerned, it will be seen that, *on the basis of the above calculations*, settlement either by continuous flow or in open septic tanks is only half as costly as chemical precipitation. It will be noted that quiescent settlement, as compared with continuous flow settlement, does not add greatly to the total annual cost, while it gives distinctly better results.

Filtration of Tank Liquor.

80. In most cases sewage must not only be settled, but must also be filtered, and it is therefore desirable to consider the cost of the preliminary process *in conjunction with* the final or filtration process.

"Strength" of the Liquors Produced.

From the data obtained at Dorking, Leeds, and Huddersfield, where chemical precipitation (continuous flow), settlement without chemicals (continuous flow) and septic tank treatment, have been compared on the same sewage, and from our general experience, we estimate the strengths* of the five tank liquors which would be produced from our hypothetical domestic sewage, and the approximate amount of suspended matter which would be contained in each, as follows :—

Preliminary Process.	* Strength of Sewage.	* Strength of Tank Liquor	Average Amount of Suspended Matter in Tank Liquor.
Quiescent settlement with chemicals	100	50	1 to 4 parts
Continuous flow settlement with chemicals	100	60	3 „ 6 „
Quiescent settlement without chemicals	100	70	5 „ 8 „
Continuous flow settlement without chemicals	100	80	10 „ 15 „
Septic tanks	100	80	10 „ 15 „

Final Purification of the Tank Liquors.

81. On the grounds set out in a later section of this report, we consider that the amount of tank liquor which can be treated on a filter depends upon the strength of the liquor and the amount of suspended matter which it contains, and further, that some filters are more suitable for the filtration of certain kinds of tank liquor than others. For the purpose of our present comparison we have selected percolating filters composed of rather coarse material, say, 1 to 3 inches in diameter. The rate of filtration at which such filters could be used with each of the five preliminary processes, so as to yield satisfactory effluents, is shown in the following table :—

Preliminary Process.	Strength of Tank Liquor.	Amount of Suspended Matter in Tank Liquor (parts per 100,000).	Rate of Filtration per cube yard per day (dry weather flow).	Cubic Content of Filtering Material required to treat 1 million gallons per day (dry weather flow).
			gallons.	cubic yards.
Quiescent settlement with chemicals	50	1 to 4	175	5,714
Continuous flow settlement with chemicals	60	3 „ 6	150	6,666
Quiescent settlement without chemicals	70	5 „ 8	100–125	8,928
Continuous flow settlement without chemicals	80	10 „ 15	75–100	11,494
Septic tanks	80	10 „ 15	75–100	11,494

* The strength is calculated on the basis of the formula suggested by Dr. McGowan, *see* page 16.

The total annual cost of five sets of percolating filters of coarse material, we have calculated to be as follows* :—

Preliminary Process.	Total Cost of Filtration, including loan charges.	
	Per annum.	Per million gallons (dry weather flow).
	£ s. d.	£ s. d.
Quiescent settlement with chemicals	572 19 7	1 11 5
Continuous flow settlement with chemicals	661 11 3	1 16 3
Quiescent settlement without chemicals	766 9 2	2 1 11
Continuous flow settlement without chemicals	960 8 5	2 12 8
Septic tanks	960 8 5	2 12 8

The total cost of the complete treatment in each case (loan charges included) would therefore be as follows :—

Per Annum.

Preliminary Process.	Total Cost of Preliminary Treatment.	Total Cost of Filtration Process.	Total Cost of complete Treatment.
	£ s. d.	£ s. d.	£ s. d.
Quiescent settlement with chemicals	1,258 0 9	572 19 7	1,831 0 4
Continuous flow settlement with chemicals	1,134 19 11	661 11 3	1,796 11 2
Quiescent settlement without chemicals	724 7 9	766 9 2	1,490 16 11
Continuous flow settlement without chemicals	564 12 8	960 8 5	1,525 1 1
Septic tanks	629 4 11	960 8 5	1,589 13 4

Per Million Gallons (dry weather flow.)

Preliminary Process.	Total Cost of Preliminary Treatment.	Total Cost of Filtration Process.	Total Cost of complete Treatment.
	£ s. d.	£ s. d.	£ s. d.
Quiescent settlement with chemicals	3 8 11	1 11 5	5 0 4

Quiescent settlement with chemicals - - - -	1,831	0	4	5	0	4

Conclusions.

82. The above figures have been arrived at by making a number of assumptions, but they are based upon a large mass of evidence and experience.

We have not had an opportunity of making comparative observations, as regards all the processes, at one place.

The figures show that there is little difference as regards annual cost between the processes of quiescent and continuous flow settlement of sewage and septic tank settlement, when these are adopted in conjunction with percolation through filters of coarse material, the maximum difference being only 6 per cent. On the other hand, the two processes of chemical precipitation are from 20 to 25 per cent. more costly than the cheapest of the simple settlement processes. As regards this point, however, it must be remarked that sewage which has undergone chemical precipitation contains less suspended and colloidal matter than sewage which has been passed through a septic tank, or than sewage which has been settled without chemicals, and therefore it can be treated on a filter of finer material, and in that case a smaller number of cubic yards of material than we have allowed for in this comparison would suffice for its purification.

In this connection, it may also be pointed out that, where sewage is freed, as far as possible, from suspended matter, a large extra quantity may, in times of storms, be passed through coarse percolating filters, without injury to the filters.*

In the absence of special circumstances favouring a particular plan, it would appear that there is very little difference in annual cost between the various methods of tank treatment followed by filtration through percolating filters, assuming that the kind of filter adopted in each case is that which is best adapted to the particular tank treatment provided.

Some Observations on the Choice of Tank Treatment.

83. The form of preliminary treatment which should be adopted at a given place should depend *mainly* upon the means at hand for the disposal of sludge, and upon the class of filter to be used in the subsequent filtration of the tank liquor. If fine filters are to be used for the oxidation of the tank liquor, the tank treatment should generally be such as will eliminate a large proportion of the suspended and colloidal matter.

We shall make some further observations on this aspect of the question in the section dealing with filters. With a tank liquor of given strength, and containing a given quantity of suspended and colloidal matter, it is of little consequence, as regards the subsequent filtration, by what method of preliminary treatment this liquor has been obtained.†

* *See* Leeds Report 1905, pp. 114, 115.

† From the result of the experiments at present in progress at Dorking, the above statement may have to be somewhat modified. The neutralisation of the sulphuretted hydrogen of the septic liquor and the slightly increased alkalinity given by the lime appear to allow of a very considerable increase in the volume which may be filtered per cube yard, greater than would follow from the mere reduction in suspended solids effected by this precipitation.

The nature of the sewage to be treated should, however, be considered in selecting the tank treatment to be adopted.

Domestic sewages may be divided into three classes, viz. :—

(1) Domestic sewages which are very strong ;

(2) Domestic sewages of about average strength ; and

(3) Weak domestic sewages.

Domestic Sewages which are very Strong.

84. Very strong sewages, derived from towns where the water-closet system is in vogue, contain more suspended and colloidal matter than weak sewages. Our analyses, so far as they go, have shown that the actual proportion of colloidal to suspended matter in sewage is not great ; but since the amount of colloidal matter is frequently somewhat larger in a septic tank liquor than in its corresponding sewage, the proportion of colloidal to suspended matter in a strong septic tank liquor may be considerable. Such a liquor would exercise a greater clogging effect upon a filter of fine or medium-sized material than its figure for " suspended solids " would lead one to expect. Moreover, the septic liquor and sludge produced from such a sewage would almost certainly give rise to considerable smell, and if the sewage contained much brewery or tannery waste the smell would be still more pronounced.

Where sewage has to be pumped its character may be abnormal. It may remain for a considerable time in the main sewer or sewers, and become " septic " in character before it reaches the outfall. Moreover, in such cases, surface water is often rigorously excluded so as to diminish the cost of pumping, and the strength of the sewage is thus increased.

In the majority of cases we think it would probably be better to adopt chemical precipitation rather than septic tanks as the preliminary process for very strong water-closet domestic sewages, and especially would this be the case if the sewage contained an appreciable quantity of brewery or tannery waste.* Precipitation with chemicals has the effect of throwing down, as sludge, a considerable proportion of the colloidal matter present, and some precipitants have the power of retarding for a short time the putrefaction of the sludge, so that precipitation sludge, if removed from the tanks at short intervals of time, can usually be disposed of with less danger of nuisance than septic tank sludge. It may also be remarked that the addition of lime to a putrid domestic sewage is followed by a great diminution of the smell.

Moreover, chemically precipitated sludge is, volume for volume, usually much less costly to press than septic tank sludge, especially if it is derived from a strong domestic sewage of the kind indicated above ; indeed the quantity of lime which has to be added to some septic tank sludges makes the cost of pressing almost prohibitive.

Simple sedimentation of a sewage of this class would also be less advantageous than chemical precipitation. Little colloidal matter would be removed from the sewage, and there would be more danger of nuisance from smell during the sludging of the tanks and the sludge disposal operations.

85. As regards very strong domestic sewages consisting for the most part of slop-water there is, apart from the question of cost, little to choose between the various methods of settlement. The bulk of the suspended matter in such a sewage settles fairly rapidly, leaving a soapy liquid containing a considerable quantity of greasy suspended matter. Such sewages are, however, usually to be found at small places where labour for frequent sludging would not be available, and in these circumstances septic tanks would usually be more economical than sedimentation or chemical precipitation tanks, and they would produce a tank liquor which would be suitable for filtration through coarse filters.

---

* The success which has attended the treatment of the Dorking septic tank liquor with a small quantity of lime makes it appear possible that in some cases the combination of the two processes—*i.e.*, septic tank treatment followed by lime precipitation—would be preferable to precipitation alone (*c.f.* paragraph 56 and note on p. 43).

We have had opportunities for observing the treatment of sewages of this kind by various methods of settlement, including septic tanks (Hemsworth), settling tanks used on the continuous flow plan (Clifton, Lancashire), and chemical precipitation followed by quiescent settlement (Withnell). The two examples of chemical precipitation followed by continuous flow settlement which we have had under observation—Calverley and Normanton (Yorkshire)—did not give very good results as regards settlement, the suspended matter in the tank liquor being above 12 parts per 100,000 in both cases. The reasons for this were that the sewage varied greatly in strength throughout the day, and the proper addition of the precipitant was a matter of much difficulty ; and, as is common at some places, the tanks were allowed to run too long without cleaning.

Domestic Sewages of about Average Strength.

86. For domestic sewages of about average strength, whether of the slop-water or water-closet type, the choice of the preliminary process should depend upon local circumstances and upon the kind of filters to be adopted. With such sewages equally good final results may be obtained either from septic, sedimentation, or chemical precipitation tanks, followed by artificial filters, though the size of the material to be used in the filter should depend, to some extent, on which tank treatment was adopted. The least amount of sludge is produced by the septic tank and the greatest amount by the chemical precipitation tank, but a larger area of filter is required for the treatment of the septic tank liquor than for the treatment of the precipitation tank liquor. Approximately the same filter area is required for the filtration of sewage from sedimentation tanks used with a continuous flow as for septic tank liquor. If quiescent sedimentation is adopted, a smaller area of filter will suffice. Excepting at very small places, where the labour costs for the constant sludging of the tanks would be disproportionately high, or in cases where pumping would be required, quiescent sedimentation gives considerably better results as regards suspended matter than continuous flow sedimentation, at practically the same cost.

Weak Domestic Sewage.

87. The last 4 or 5 parts of suspended matter are extremely difficult to throw down as sludge, and in the case of weak sewages the difference between the various tank treatments, as regards suspended matter in the resulting liquors, is not nearly so great as it is in the case of strong sewage.

For this reason, the advantage as regards amount of sludge produced and saving in cost of chemicals which the preliminary processes of septic tank treatment and continuous flow sedimentation have over chemical precipitation, is of greater importance with weak than with strong sewages. The septic tank process would, we think, generally be most economical for a weak sewage, if land were available for the burial of the sludge. The sludge produced would not have a very offensive smell, and might indeed in some cases be comparatively free from smell. If, however, no land were available for the burial of the sludge, the extra cost of pressing septic tank sludge would materially diminish the advantage of septic tank treatment.

Summary for Domestic Sewage.

88. Speaking generally, we should say that chemical precipitation is more suitable for strong sewages or sewages likely to give rise to nuisance, while septic tank treatment or sedimentation would usually hold the advantage in the case of weak sewage. For sewage of about average strength there is probably little difference between the three processes, and the selection of the process would depend chiefly upon the facilities for sludge disposal, the position of the works as regards houses, and the kind of filters to be adopted.

It must be remembered, however, that there are other considerations which may affect the question. A particular sewage, for example, may be liable to great variations in strength and character, and the equalising effect which the septic tank has on such a sewage is a point of considerable importance.

Moreover, it is by no means to be thought that finality has been reached in the preliminary treatment of sewage. New combinations of tanks or of processes may lead to much improvement; a cheap deodorant for sludge may be found, etc. In this connection, we may refer to the results of our experiments at Dorking upon the treatment of sewage by septic tanks, followed by precipitation with lime, which are mentioned on p. 29.

Sewage from large Cities.

89. The presence of trade waste in large or preponderating quantity has an important bearing upon the preliminary treatment of the sewage from a large city. Where the sewage contained much brewery waste, lime would probably have to be added for the purpose of neutralisation, as at Burton-on-Trent; where it was strongly alkaline, or very greasy, acid might have to be used as the precipitant, as at Bradford; where it contained much tarry matter or matter which had an inhibitory effect upon the activity of purifying organisms, septic tanks might be preferable, by reason of the longer stay which they give to the sewage. Manchester may be cited as an example of this last case. For these reasons it is impossible to make any but the broadest generalisations with regard to the preliminary treatment of the sewage from large cities, whether it be weak or strong.

Where very large areas of filters have to be put down, it is of considerable importance to protect them against clogging, and we think that it will usually be found best in the case of a large city to adopt effective means for the removal of most of the suspended matter before filtration. In the majority of cases this would involve the adoption of chemical precipitation, though not necessarily in all, for Mr. Watson, of Birmingham, has shown that a well clarified tank liquor can be obtained by interposing Dortmund tanks between the septic tanks and the filters. The Birmingham septic liquor contains on the average about 20 parts of suspended matter before entering the Dortmund tanks, but only about 6 parts when it leaves them. This liquor from the Dortmund tanks has now been treated for some years on percolating filters without serious clogging. It must be pointed out as regards Birmingham, however, that at that place there is a very large area of land available for the disposal of sludge. If it were not for this, sludge pressing might have been necessary, and having regard to the difficulty of pressing septic tank sludge, it might have been desirable to adopt chemical precipitation.

PART II.—PURIFICATION OF SEWAGE BY ARTIFICIAL FILTERS.

INTRODUCTORY REMARKS.

90. Sewage filters may be divided into two broad classes:—contact beds and percolating filters.

Contact beds are tanks filled with some filtering medium. In this type of filter, the sewage is held up before it is discharged. The bed, after it is emptied, is allowed to remain empty for some time before receiving the next filling. The length of time during which the sewage is allowed to stand in the bed is spoken of as the period of contact.

In percolating filters the sewage is not held up, but is allowed to percolate through the filter.

There can be no doubt that the organic matter in solution in sewage can be oxidised by either type of filter, provided the filter is properly constructed and properly worked, but the question of the relative merits of the two types is one of some difficulty, as very few strictly comparative experiments on a large scale have been made.

SOME OBSERVATIONS AS TO THE EXTENT TO WHICH THE SUSPENDED SOLIDS SHOULD BE REMOVED FROM SEWAGE BEFORE IT IS FILTERED.

91. No rule can be laid down as to the extent to which the suspended solids should be removed from sewage before it is filtered, but, speaking generally, if it is proposed to use filters of fine material, we think it will be found most economical to adopt some form of tank treatment which will yield a tank liquor fairly free from suspended solids; whereas, if coarse filtering material is to be used, this is not so essential.

If much suspended matter is put on fine filters, they are likely to choke very rapidly unless the rate of filtration is very slow.

Under the heading "Some observations on the choice of a method of sewage treatment," page 202, a number of points are mentioned which should be taken into account in determining what method of treatment should be adopted in any particular place, and in this section we only propose to give the results of our general experience as to the amounts of suspended matter, which, having due regard to the life of the filter and to the quality of effluent, may be allowed with certain kinds of filters, worked at certain rates.

The figures relate to domestic sewage, or sewage containing only small amounts of trade refuse, of average strength.

The rates of filtration which we give could generally be doubled in wet weather. Thus, assuming it was desired to provide enough filtering material to filter in storm times up to three times the dry weather flow of sewage, the amount of material required would be 50 per cent. more than the amount which would be required for the dry weather flow, calculated on our figures.

I.—Contact Beds.

Coarse Material (3 ins. diameter and upwards).

92. Grit-settled sewage containing 20 to 30 parts of suspended matter could be treated at the rate of 1 to 1½ fillings per day (about 30 to 40 gallons per cube yard* per day for double contact) upon material of this size in contact beds; if the sewage contained 30 to 50 parts of suspended matter per 100,000, the rate of treatment should not exceed 1 filling per day (about 30 gallons per cube yard per day for double contact). In both cases provision would have to be made for thoroughly washing the material in the beds about once every 18 months or 2 years. Secondary beds of medium-sized material, used subsequently, would probably have to be washed every 4 or 6 years.

Medium-sized Material (½ in. to 1 in. diameter).

93. Tank liquors containing 10 to 15 parts of suspended matter per 100,000 could be treated upon material of this size at the rate of about 2 fillings per day (50 gallons per cube yard* of filtering material per day for double contact, or 100 gallons per cube yard for single contact), but the material would have to be thoroughly washed or renewed every 3 to 5 years. If the tank liquor contained from 4 to 7 parts of suspended matter per 100,000, the rate of treatment might be 3 (about 80 gallons per cube yard* per day for double contact, or 160 gallons per cube yard for single contact) or, at times, 4 fillings per day, and the beds would probably have to be washed every 4 or 5 years. In both these cases the material in the secondary beds would probably not require to be washed for 7 or 8 years.

* See footnote on next page.

If the liquor contained from 1 to 4 parts of suspended matter per 100,000 it could probably be treated at a rate of 4 to 6 † fillings per 24 hours (about 100 to 160 gallons per cube yard * per day, for double contact), and the material might not need washing for 6 to 8 years, or possibly even longer. Secondary beds, in this case, would probably last for 12 or 15 years.

Fine Material ($\frac{1}{4}$ *in. diameter*).

94. It would be inadvisable, we think, to attempt to treat tank liquors containing more than 4 or 5 parts of suspended matter per 100,000, on material of this size. A good tank liquor, containing from 1 to 4 parts of suspended matter could, probably, be well filtered at the rate of from 4 to 6 * fillings per day (about 100 to 160 gallons per cube yard † per day for double contact or 200 to 320 gallons per cube yard for single contact), and the material would, probably, not have to be washed for 6 or 8 years. The upper part of the material in secondary beds would, probably, have to be washed every 12 or 15 years.

II.—Percolating Filters.

Coarse Material (3 *in. diameter and upwards*).

95. Grit-settled and screened sewage could be treated on a percolating filter composed of material of this size even if it contained as much as 30 parts of suspended matter per 100,000, provided such suspended matter was not largely made up of fibrous material, hops, etc. If the sewage was of average strength, it could, probably, be filtered at a rate of about 50 gallons per cube yard per day. The upper part of the material would, we think, have to be removed and replaced about every 2 years, and the lower part flushed through with water or clarified sewage.

Tank liquors containing, say, 10 to 20 parts of suspended matter per 100,000, might be treated upon this material for long periods of time (say, 10 to 15 years) with occasional renewal of the top foot of material. If the tank liquor was of about average strength, it could be filtered at a rate of about 100 gallons per cube yard per day.

A tank liquor of about average strength, containing from 4 to 7 parts of suspended matter per 100,000, could similarly be treated on coarse material, but in this case the rate of filtration might be about 100 to 150 gallons per cube yard per day.

A tank liquor, containing from 1 to 4 parts of suspended matter per 100,000, could be filtered for even longer periods of time on coarse material, and, if it were of about average strength, at a rate of 150 or possibly 200 gallons per cube yard per day.

In all these cases the filtration might occasionally be affected by fungoid growths on the surfaces of the filters. Provision would generally have to be made in the first three cases, and possibly in the last also, for the settlement or the straining, through fine material, of the filter effluent, in order to reduce the suspended matter contained in it.

Medium-sized Material ($\frac{1}{2}$ *in. to* 1 *in. diameter*).

96. Grit-settled and thoroughly screened sewage could generally be treated upon material of this size, even though it contained as much as 30 parts of suspended matter per 100,000. The rate of filtration, however, should not exceed 25 gallons per cube yard per day, and even in that case the upper part of the material would probably require to be washed every 2 or 3 years. The plan would, we think, not be economical, except at very small places.

---

* There are good grounds for putting the average water capacity of a primary contact bed during its working life at about 33 per cent. of its original empty tank capacity. These estimates are consequently based upon that assumption. We estimate that the average capacity of a secondary bed during the lifetime of its complementary primary bed, is about 40 per cent. of its original empty tank capacity. If this is taken into account, *i.e.*, if the secondary beds are made proportionately smaller than the primary beds, the rates of filtration per cube yard per day will be rather greater in each of the cases given above.

† With large beds such a high rate of working would, probably, be only practicable for short periods of time.

Tank liquors containing from 10 to 15 parts of suspended matter per 100,000 could generally be treated on this material at a rate of about 50 gallons per cube yard per day, if the upper part of the material were washed or renewed once in 3 or 4 years, and provided also that the bed were well rested immediately any signs of ponding occurred.

A tank liquor containing from 4 to 7 parts of suspended matter per 100,000 could generally be filtered at a rate of 75 to 100 gallons per cube yard per day. The upper part of the material would probably require washing or renewal once in 3 to 5 years.

A very good tank liquor containing from 1 to 4 parts of suspended matter could generally be filtered at a rate of 150 to 200 gallons per cube yard per day, provided the filter were carefully rested when necessary, and also that the liquor was not of a kind liable to give rise to fungoid growths. The material in this case would probably last without washing for 5 or 6 years, or possibly even longer, though it might be advisable to wash or renew the uppermost few inches every 1 or 2 years.

In the first three mentioned cases, and possibly in the last also, provision would usually have to be made for the reduction of the suspended matter in the filter effluent.

Fine Material ($\frac{1}{4}$ *in. diameter*).

97. It would be inadvisable, we think, to attempt to filter tank liquors containing more than 6 or 7 parts of suspended matter per 100,000 on material as fine as this. Crude sewage, for instance, would clog the surface of such material in a very short time, unless the rate of filtration were exceedingly slow, and even then the surface of the material would have to be constantly scraped and cleaned.

Tank liquors containing from 4 to 7 parts of suspended matter per 100,000 could generally be filtered at a rate of 75 to 100 gallons per cube yard per day. The upper part of the material would require washing or renewal about once in 4 or 5 years.

A tank liquor containing from 1 to 4 parts of suspended matter per 100,000 could probably be filtered at a rate of 150 to 200 gallons per cube yard per day, and the material in the upper part of the filter would probably require washing once in 4 or 5 years. The higher rate could only be maintained, if the filters were shallow.

Very fine Material ($\frac{1}{8}$ *in. diameter and smaller*).

98. Where material, such as sand, is used for a filter, or where the filter is protected with a surface layer of sand, only very well clarified tank liquors can be treated, unless the rate of filtration is very slow and the surfaces of the beds are scraped or washed at short intervals. Such filters must necessarily be used intermittently.

For tank liquors containing from 4 to 7 parts of suspended matter per 100,000, the rate of filtration should probably not exceed 50 gallons per cube yard per day, and the surfaces of the filters would have to be scraped after every one or two applications of the liquor. If the fine material alone were relied upon for the distribution of the liquid, the rate of filtration might possibly have to be slower. If very fine-grained filters were arranged in the shallow form and were washed by upward flow every one or two weeks, it would be possible to treat a very good tank liquor from a sewage of about average strength, containing, say, 1 to 4 parts of suspended matter per 100,000, at rates of from 200 to 300 gallons per cube yard per 24 hours. The liquor would have to be delivered intermittently, and the distribution must of course be efficient. At Chorley, where such a tank liquor is delivered on to filters of this kind, the rate of filtration is upwards of 350 gallons per cube yard per day. Here, the tank liquor is delivered in large flushes which cover the whole surface of each bed to a depth of 2 or 3 inches, and the surface of the beds is frequently washed.

CONTACT BEDS.

99. Our knowledge of the action of a contact bed is very incomplete, and little is known as to the manner in which the organic substances of sewage are broken down during the first stages of fermentation into carbon dioxide, ammonia, etc. The purifying agents seem to be not only bacteria, but also worms, larvæ, insects, etc., and we can offer no opinion as to the respective amount of work done by each set of agents. It probably differs to some extent according to the nature of the sewage. It has been observed that at some places large numbers of worms are present, while at others there are comparatively few. Little is known of the kind of bacteria essential for purification, or as to their mode of action, and we are not able to state whether they act chiefly during the period of contact or during the period of rest, or aeration, after the filter is emptied. There are, however, grounds for thinking that the resting period is the more important phase of the cycle.

The generally accepted theory as regards nitrogenous matter seems to be that the ammonia is extracted from the liquid during the period of contact, and oxidized during the period of rest, and that the resulting nitrate and nitrite are diffused through the liquid of a subsequent filling. All the ammoniacal nitrogen, however, does not appear in the effluent in the oxidized state, for there is always loss of nitrogen, as nitrogen gas, during the process.

The withdrawal of suspended and colloidal matter from the sewage during its passage through the bed appears not to be a simple mechanical effect of the material, for a matured contact bed, not clogged, will withdraw more suspended matter from the sewage than another bed similar in all other respects, but not matured. As regards the action which takes place in a contact bed, we may also refer to the evidence of Mr. Dibdin, Dr. Rideal, Mr. Harrison, Mr. Valentine and Dr. Fowler.

Fowler, 22815.

Construction of Contact Beds.

100. In some cases contact beds have been made by simple excavation, but our experience and the evidence which we have received show that in the majority of cases it is desirable that the beds should be constructed of building materials.

When contact beds are constructed by simple excavation in clay soil, there is risk of the clay sooner or later, according to the character of the stratum, working up into the filtering material. Moreover, the lines of underdrains are apt to become distorted, as the result of unequal settlement.

Wilkinson, 24282.
Wike, 23588.

At Heywood an experimental bed was constructed, without concrete, in clay soil, and it was found that the clay worked up into the bed and formed an impervious mass round the drain pipes.

Again, there is danger of leakage unless the soil is of a very dense nature and the embankments are of considerable width. This leakage may occur as a result of unequal settlement, or through rats or moles burrowing into the embankment, or through the cracking of the clay during periods of rest or frost. The result of leakage may be detrimental to the working of the bed. Two instances which have come under our own observation may be mentioned.

At Halton it was found necessary to fill two of the primary contact beds simultaneously, as the liquid percolated from one bed to the other through the intermediate embankment.

At Oswestry, where double contact beds were constructed in fairly stiff clay soil, some of the retaining banks became sodden with liquid after three or four years' work and sank considerably in consequence.

Even in the most impervious kind of soil the outlet chambers of contact beds must be constructed of building materials, and, unless this work is most carefully carried out, there is danger of leakage at the juncture of the chamber and the embankment. It may also be remarked that the embankments required, where no building materials are used, take up more space than properly built walls.

On the other hand, where the site for the works consists of a dense clay, experience shows that the construction of contact beds by simple excavation may be satisfactory.

As examples, we may refer to the beds at Burnley and Oldham.

At Burnley twenty-four acres of double contact beds have been constructed by simple excavation in loam and heavy clay soil. The oldest of the Burnley beds was brought into use about ten years ago.

At Oldham, where the soil is chiefly clay, with pockets of sand in places, five acres of single contact beds have been constructed by simple excavation, the sides being puddled where necessary and boarded up with 3-inch planking.

In both these cases the construction has been fairly satisfactory.

101. The construction of the bottom of a contact bed should be such as to allow of the treated liquid being drawn off quickly, but quietly, in order to give the material the longest possible rest and aeration.

The liquid which, at the commencement of the filling, finds its way into the drains of a contact bed is not purified to the same degree as the bulk of the liquid throughout the filtering material, and, for this reason, the drains of a contact bed should not be larger than is necessary to allow of the thorough draining of the bed.*

It has been suggested that this difficulty of unequal purification might, to some extent, be overcome by constructing the drains so that they would remain full of filter effluent after the bed had been run off. We are not aware that this course has been actually tried, but if it were adopted, great care would have to be taken to construct the drains below the level of the material, and to place the outlet valve in such a position as to preclude the possibility of effluent standing amongst the lower layers of the material during the resting period. Whether the aeration of the bed, during the "rest," would be affected we are unable to say. In any case it would be inadvisable to attempt this plan of draining where the bottom was not constructed of concrete or some such material.

In order that the withdrawal of the liquid may be gentle, as well as rapid, it is desirable to provide several drains, especially in a large bed.

102. Two points of detail may be mentioned here which are of some importance :—

The outlet valve of a contact bed should be fixed in such a position that a proper sample of the filter effluent can be collected from it. In a number of cases we have found it very difficult to draw proper samples of effluent from contact beds, owing to the outlet valves being placed low down in the channel along which effluents from other beds were flowing, and in these cases it has not been easy to ascertain the efficiency of the individual beds.

The feed channels to the secondary beds should be constructed so as to provide reasonable facilities for measuring the capacity of the beds. These beds are frequently so constructed that accurate measurements of capacity cannot be made.

Depth of Contact Beds.

103. The evidence shows that, within ordinary limits, the depth of a contact bed makes, practically, no difference to its efficiency per cube yard.

At Leeds, experiments were made with three contact beds of different depths, filled with similar material, and treating the same tank liquor. These beds were, respectively, 5 feet deep, 4 feet deep, and 3 feet 6 inches deep.

The bed 5 feet in depth received septic tank liquor at the rate of two fillings per day, with one week's rest in every four. During the period from July, 1901, to March, 1905, the effluent showed, according to Mr. Harrison's analyses, an average reduction of 78·6 per cent. in oxygen absorbed from permanganate in four hours.

* *Note.*—The actual size of the drains would depend to some extent upon the size of the material.

The bed 4 feet deep received septic tank liquor at the rate of one filling per 24 hours, from August 17th, 1901, to January 11th, 1905. The effluent showed an average reduction in oxygen absorbed from permanganate in four hours of 80·3 per cent.

The bed 3 feet 6 inches deep received septic tank liquor for fourteen months, at a rate of three fillings per day, and gave an average reduction in oxygen absorbed from permanganate in four hours of 74 per cent.

Taking into account the differences in working, there was no great difference in the results obtained in this experiment, and so far as we could judge from a careful comparison of the results at the time the experiments were made, none which could be ascribed to the depth of the filters.

The experience of Dr. Clowes in connection with some experiments which he carried out at the London sewage works was in agreement with that of the Leeds experiments.

For further details on this question reference may be made to the evidence of Mr. Harrison, 22005; Mr. Valentine, 22450; Dr. Fowler, 22792; Mr. Wyke, 23599; Mr. Wilkinson, 24283; Mr. Campbell, 21652 and 21883; and Dr. J. B. Wilkinson, 22643.

104. From our own experience of contact beds, we think that it would be generally inadvisable to construct them of a greater depth than 6 feet or of a less depth than 2 feet 6 inches.

In order that a contact bed may drain properly, it is necessary to have a few inches of large material on the floor of the bed, and this material, with the drains themselves, would occupy about 6 inches of depth. The sewage which remains among this coarse material, or in the drain spaces, during the time when the bed is full, is not so well purified as the liquor which is standing amongst the finer material in the upper part of the bed, and it is found that the first flush from a contact bed, which comes from the lowest part of the bed, is usually considerably worse than the main bulk of the effluent. As a general rule, we doubt whether it would be wise to allow this less efficient portion of the bed to form more than one-fifth of the whole depth, and for this reason we suggest that the minimum depth should usually be not less than 2 feet 6 inches.

As regards the maximum depth of contact beds we may observe :—

(*a*) That an increase in depth puts a greater weight upon the filtering material in the lower part of the bed, and may cause disintegration.

(*b*) That the difficulty of digging and handling the material, when washing is necessary, is greater with deep than with shallow beds, and that the operation would require a greater amount of labour and would result in more breaking down of the material during the process.

105. Our experience of contact beds ranges from the deepest of the Leeds beds, 6 feet deep, to the shallow contact beds at Oldham, 1 foot 6 inches deep, the depths of the contact beds at the various places which we have had under observation being :—

Leeds	From 6 feet to 3 feet.
Exeter (St. Leonards)	5 feet.
Hendon	5 feet (about).
Slaithwaite	5 feet.
Withnell	5 feet and 3 feet 6 inches.
Oswestry	4 feet 6 inches.
Exeter (Main works)	4 feet 6 inches.
Maidstone	4 feet 4 inches and 3 feet 3 inches.
Halton	4 feet 3 inches and 3 feet 3 inches.
Hartley Wintney	4 feet.
Andover	4 feet.

Hampton	4 feet.
Newton-le-Willows	3 feet 6 inches.
Calverley	3 feet.
Guildford	2 feet 6 inches.
Oldham	1 foot 6 inches.

Filling and Emptying of Contact Beds.

106. The evidence shows that two hours' contact and four hours' rest have generally been found to give the best results in practical working, where the beds are filled three times a day, but no rule can be laid down which is of universal application.

As regards this question Dr. Fowler stated in reference to his Manchester experience that the periods depend almost "entirely on the age of the bed and the dilution of the
Fowler, 22798 "sewage. In the initial stages of working, long contacts (*e.g.*, twenty-four hours) have been "found advantageous, their effect being to facilitate the formation of a slimy layer of col- "loidal matter on the medium, in which the real biological action begins. As this layer "increases, the 'absorptive' effect increases also, and less time of contact is required. More- "over, a greater quantity of water is held up in a bed, and the quantity of 'draining' in- "creases, till with a bed in long use a very short contact, say, a quarter of an hour, is all "that is required. With increase in dilution of the tank effluent, due, *e.g.*, to storm water, "the period of contact may be reduced to a minimum. In general, after the bed is once "'mature,' the period of rest is more important than the period of contact, and the total "time occupied in twenty-four hours in filling, standing full, and emptying should not "exceed the total of the period of rest. Thus, with frequent fillings, the time of contact "should be shortened. If the bed takes long to fill, the extra time in filling should be taken "from the time of contact. The above also applies to secondary beds, it being understood "that, as they deal with an effluent containing less impurity, they can be worked more "rapidly than primary beds."

At Calverley the period occupied by filling and standing full varied from six to twenty-four hours, the beds being filled, on an average, less than once a day. A good percentage purification on a strong precipitation liquor was obtained by single contact, but the liquor was too strong to allow of single contact producing a satisfactory effluent. The beds retained their capacity well. A long contact apparently helps to break down the suspended solids and to allow of their passing out of the beds in very considerable quantity.

107. Unless the circumstances are exceptional, we think that, in designing a contact bed scheme, a contact of two hours' duration should be provided for, leaving subsequent experience to show whether this could not be shortened to some extent. The period of contact should be fairly regular, as sudden variations may, we think, have a disturbing effect upon the agents of purification. We have noticed, for instance, in beds generally giving two hours' contact, that if the sewage is occasionally held up for a much longer time, say, five or six hours, great numbers of worms are driven to the surface.

It is also desirable that the fillings should be as far apart from one another as practicable, (*e.g.*, to give three fillings in three cycles of eight hours each, rather than three fillings in twelve hours followed by a twelve hours' rest), so that the maximum period for drainage and aeration between the fillings may be obtained.

108. The operations of filling and emptying should be carried out as rapidly as possible, but care must be taken to avoid disturbance of the filtering material, as this may cause disintegration.

Harding, 7051. *et seq.* Ross and Pickles, 2077. Harrison, Fowler, 22799. Wike, 23565. Wilkinson, 24920.

Further, the evidence shows that the liquid should be passed on to the filter fairly evenly over its whole surface, so that the suspended solids may, as far as practicable, be spread over the whole surface and prevented from entering the bed.

109. With a view to avoiding nuisance, the feed channels have, in some few cases, been placed slightly below the surface of the material, and no doubt the smell from the beds has been thereby lessened. But beds fed in this way would, we think, require more frequent attention to prevent clogging.

In one or two cases upward filling of contact beds has been suggested for a similar reason. This method of filling would, no doubt, lessen the risk of nuisance, but the difficulty of maintaining the capacity of beds worked in this way would be serious.

Automatic Gear.

110. We have had many opportunities of studying the use of automatic apparatus for filling and emptying contact beds, and we have received evidence from several witnesses who have had considerable experience of these devices.

Our own observations and the experience of others show that it is not possible to rely entirely on automatic apparatus for sewage works, although within certain limits it may be advantageously used with considerable saving of labour.

In the case of large sewage disposal works, where men are always available, we consider that it would usually be inexpedient to provide automatic plant. It is liable to get out of order, it does not adapt itself to variations in volume and strength of sewage, state of beds, etc., and generally it is preferable to work the beds by manual labour, where such labour is at hand.

At Manchester, automatic gear was given a careful trial, with a view to its ultimate adoption, if successful. It had, however, to be abandoned, and in reference to this Dr. G. J. Fowler stated :—

> "I have had considerable experience of these devices, both on the experi- Fowler, 22800.
> "mental and working scale at the Davyhulme works, and also at the Withington
> "works. My experience leads me to think that in large works, where skilled
> "supervision must be provided in any case, there is no advantage in their use.
>
> "In small works I think some simple mechanism is useful, chiefly on
> "economic grounds, but it should not be left without some attention, if pos-
> "sible, at least once a day. In small works, with the filtering area divided into
> "few units, great fluctuations may occur in the cycle unless some arrangement
> "of dosing tank is provided, or storage in the main tank (septic or other). These
> "fluctuations may be harmful by causing the time of filling to be too prolonged,
> "with consequent curtailment of the resting period. The chief difficulty, how-
> "ever, is the constant variation in the water-holding capacity of the beds and
> "in the permeability of the surface, causing pondage and irregular working."

We may also refer to the evidence of Messrs. Raymond Ross and Pickles in regard to to the Burnley works. They stated :— Ross and Pickles, 20778.

> "We have not used any automatic apparatus for filling or discharging.
> "The reasons which have led to the exclusion of automatic apparatus are as
> "follows :—
>
> (1) "They are very liable to get out of order, and consequently it is necessary
> "to have a man always on the watch to see that they are working properly.
> "As the attendance of one man is all that is required at our works
> "to control the valves, no saving of wages would be effected, but there
> "would be considerable increase in capital outlay, as all the appliances
> "are expensive to instal, and, we think, costly to maintain.
>
> (2) "Automatic apparatus takes no notice of the condition of the bed, which,
> "in our opinion, is a matter of considerable importance.
>
> (3) "Where the flow of sewage varies, it is desirable to be able to bring the
> "larger beds into use during the time of the greatest flow, so that their
> "period of filling may approximately equal that of the smaller beds. This,
> "we consider, is best accomplished by hand control."

Similar evidence was given by other witnesses.

In the case of small sewage works, however, where labour would not always be available, automatic gear for filling and emptying the beds would often effect considerable saving. Where automatic gear is provided, proper arrangements should be made for the treatment of storm water or sewage overflow arising from a breakdown in the gear. In no case can personal attention be dispensed with entirely.

Loss of Capacity of Contact Beds.

111. The loss of capacity of contact beds is undoubtedly a serious drawback to their efficiency. The evidence shows that the loss chiefly depends upon the following factors:—

(1) Disintegration of the filtering material.
(2) Consolidation of the filtering material.
(3) Deposition of colloidal matter.
(4) Growth of organisms.
(5) The volume of liquid passed on to the bed.
(6) Insufficient rest.
(7) Inefficient drainage.
(8) The amount of suspended matter in the liquid passed on to the bed.

(1) *Disintegration of the Filtering Material.*

112. In the experiments made by Colonel T. W. Harding and Mr. W. H. Harrison at Leeds, the material in nearly all the contact beds was found to have disintegrated considerably.

One of the first of these experiments related to the treatment of crude sewage on contact beds, filled with particles of coke over 3 inches in diameter. This experiment lasted from October 2nd, 1897, to September 8th, 1898, and the coke, in both the primary and secondary beds, suffered considerable disintegration. When the experiment was completed, the material in the primary beds was taken out and only that coke replaced which could not pass through a $1\frac{1}{2}$ inch mesh. Colonel Harding and Mr. Harrison computed the volume of coke rejected in this way at 45·25 per cent. They concluded that if a material could have been used which was not liable to degradation, probably one-third of the loss of capacity would have been avoided.

In the clinker beds, crude sewage, chemically precipitated sewage, and septic tank liquor were treated, and in the case of these beds, also, considerable disintegration took place.

At Hartley Wintney, where soft furnace clinker was used, we observed that the material had disintegrated considerably after five years' work, and we came to the conclusion that this was one of the chief causes of loss of capacity of contact beds at that place.

At Burnley, where a large area of contact beds has been in use for some years, it has been found that the disintegration of the material has caused a considerable loss of capacity. The experience of Burnley, however, has shown that much of the material which has broken down in primary beds may be used with advantage in secondary beds, and that beds which are filled with old material, after it has been washed and re-screened, do not lose capacity so rapidly as beds constructed of new material.

The experience of Manchester in regard to the disintegration of material is also of value. The following data have been given to us as representing a typical case:—

Contact bed No. 10 was first brought into use on May 2nd, 1902, the bulk of the material of which it was composed consisting of dry screened boiler clinker and cinders rejected by a $\frac{3}{16}$ inch mesh. There was also large clinker over the line of drains. After having received 2,578 fillings the bed was stopped, and the whole of the material was washed against a $\frac{1}{4}$ inch mesh sieve. As a result of this screening, 24·1 per cent. of the material was found to be too small to go back into the bed. About two-thirds of this was $\frac{1}{8}$ to $\frac{1}{4}$ inch in size, and was available for the surface of the secondary beds. The actual loss of material, after allowing for the re-use of the material on secondary beds, was estimated by Dr. Fowler at about 8 per cent. to 10 per cent. of the original material.

At Newton-le-Willows, the material (furnace clinker) in all the contact beds at the central works was taken out and re-screened after six years' use. In June, 1900, when the beds were first brought into operation, the material consisted of particles from $\frac{1}{2}$ inch to 2 inches diameter. As a result of the re-screening, which took place between March and September, 1906, Mr. Arthur Bowes, the Surveyor to the Newton-in-Makerfield Urban District Council, estimated that about 25 per cent. was too small to be used again.

At Andover, a bed which was under observation by Mr. R. W. Knapp, was first brought into use on August 13th, 1901, the bulk of the material (hard furnace clinker) being, at that time, from $\frac{1}{8}$ inch to $\frac{1}{2}$ inch diameter. In August, 1905, the bed was stopped and the material taken out and riddled, with the result that only 75 per cent. was found to be still $\frac{1}{8}$ inch to $\frac{1}{2}$ inch in diameter. The remainder had become too small to go back into the bed.

At Oswestry, where ordinary house cinders were used in the primary beds, considerable disintegration took place after about six years' working.

These, and other experiments, leave no room for doubt that a considerable proportion of the loss of capacity of contact beds is due to the disintegration of the material of which the bed is formed.

(2) *Consolidation of the Filtering Material.*

113. Consolidation of the material usually accompanies its disintegration, the small broken pieces becoming washed into the interspaces of the bed. The same thing takes place where the separate fragments of material in a bed are of unequal size.

In the Leeds experiments it was found that contact bed No. 8, treating septic tank liquor, had its capacity reduced within six months from 29,500 gallons to 10,700 gallons, and this notwithstanding that the material below the upper 2 inches was still comparatively clean.

The bed was rested for six weeks, and the material turned over, with the result that on restarting the capacity was found to be 26,900 gallons. The material in this bed was furnace clinker of $\frac{1}{8}$ inch to $\frac{3}{8}$ inch diameter.

Much the same result was noticed during the filtration of lime-precipitated liquor at Leeds in a contact bed. The original water capacity of this bed, on March 24th, 1899, was 55,700 gallons ; on October 20th, 1899, after rather over seven months' working at three fillings per 24 hours, it had fallen to 21,600 gallons. Here again the material (clinker of $\frac{5}{8}$ inch to 1 inch diameter) below the upper few inches was found to be fairly clean, though much consolidated.

It was concluded that the loss of capacity in both cases was due very largely to consolidation of fine material of uneven size, and our own observations of these beds bear this out.

In another case—Hampton—where very much finer material was used, the same thing was observed. Tertiary bed No. 2, composed of boiler furnace clinker under $\frac{1}{4}$ inch diameter, including dust, after being in use for five years, became so consolidated that much difficulty was experienced in getting the secondary bed effluent into it. The bed was then simply turned over, and a considerable increase of capacity resulted. From the appearance of the material before it was turned over (which although clean, was closely bound together), it was evident that the greater part of the loss of capacity was due to the consolidation of the material rather than to clogging from suspended matter.

Beds of very fine material, as in this case, are undoubtedly more liable to consolidation than beds of medium sized or large material. In some beds of the same kind at Devizes, we observed that the fine material (which also included dust), although fairly clean, was so closely bound together that the liquid of one filling had not time to run away before the next filling was due, with the result that putrefaction set up in the body of the bed.

(3) *Deposition of Colloidal Matter.*

114. The extent to which colloidal matter affects the capacity of filter beds has not been fully investigated, but we are satisfied that in some cases it is serious. Dr. Fowler was, we believe, one of the first to investigate the matter in this country, and it has recently been the subject of investigation by Dr. Owen Travis at Hampton, and Messrs. O'Shaughnessy and Kinnersley at Birmingham.

(4) *Growth of Organisms.*

115. If a piece of clean filtering material is taken out of the interior of a matured contact bed and scraped, its surface will be found to be covered with a jelly-like material, which, under the microscope, is seen to contain enormous numbers of bacteria. This material possesses the power of absorbing oxygen rapidly and liberating carbon dioxide. It is probable that it is the living matter bound up in this jelly which gives the bed power to break down and oxidise the organic matter of impure liquids, but little is known about its precise nature and manner of action.

Several witnesses have expressed the view that the growth of organisms is one of the causes of loss of capacity in a contact bed.

In regard to this point Dr. Fowler stated :—

Fowler, 22803.

> " This (growth of organisms) is at once the cause of increased efficiency in " the bed, and of loss of capacity. On examining the material of a contact bed " in active condition, every piece is seen to be coated over with a slimy growth. " If this is removed it soon dries to a stiff jelly, which can be cut with a knife. " Under the microscope masses of bacteria and zoogloœa will be found to be " present. If placed in a tube containing air, and connected with a manometer, " the jelly will rapidly absorb all the oxygen and produce carbon dioxide.
>
> " This action will sometimes produce a vacuum of several inches of mercury. " There is little need, therefore, to force air into a bed, as the natural interchange " of gases which takes place is sufficient for adequate aeration. As a matter " of fact, there is always a large amount of oxygen to be found at the bottom of " a bed in good condition. The behaviour of the bacterial jelly appears to afford " the clue to the successful working of bacteria beds. By working them at a high " speed—*i.e.*, filling them frequently in the day, without long periods of rest— " the effluent may remain good, but the bacterial growth so rapidly increases " that the bed becomes too spongy, and will not allow the water to drain away. " Here, too, is the explanation of the fact that, within certain limits, decrease of " capacity is accompanied by increase of efficiency.
>
> " This decrease of capacity may, however, become so great as to outweigh " the advantage of increased efficiency. A long period, say one or two weeks' " rest, must then be given to the bed.
>
> " These rests should not exceed a fortnight at most, as the bed then tends to " dry up, and the activity of the organisms diminishes.
>
> " It is therefore important that the decrease of capacity should not be " allowed to become excessive before resting, or it may not be possible to com- " pletely recover the loss during the time of rest."

(5) *The Volume of Liquid passed on to the Bed.* (6) *Insufficient rest.* (7) *Inefficient drainage.*

116. It is evident that, for physical reasons alone, the working capacity of a contact bed must be influenced to some extent by the actual volume of liquid treated. If, for instance, two exactly similar contact beds, filled with unmatured material of the same size, are fed with pure water, one being given eight fillings and the other two fillings per day, the former, although not losing capacity in the absolute sense, will take rather less water at each filling than the latter, owing to the less time allowed for drainage between the fillings.

We do not suggest that the water held in a clean and unmatured bed by capillary attraction, after the bed is emptied, has a serious practical effect upon the working capacity of a bed; but with a matured contact bed containing jelly-like masses of bacteria as well as sewage suspended matter in a very spongy state, the time allowed for drainage becomes a question of importance, and the volume of liquid dealt with, in practice, affects the capacity of contact beds. A rather larger quantity of filtering material would, for instance, be advisable at a sewage works, where two volumes of weak sewage were to be treated in contact beds, than at another where one volume of sewage, of twice the strength, had to be dealt with.

117. The value of rest to a contact bed in helping it to maintain its water capacity is well known. We may cite two cases; one relating to the treatment of a manufacturing sewage (Leeds), and the other to the treatment of a purely domestic sewage (Hampton).

Leeds.—During the experiments upon the filtration of Leeds crude sewage, the primary bed, which started on October 2nd, 1897, with a water capacity of 83,000 gallons, had been reduced by February 2nd, 1898, to 45,000 gallons capacity. After a fortnight's rest its capacity was again measured, and found to be 56,000 gallons, or an increase of 11,000 gallons.

A similar increase of capacity followed subsequent rests.

Hampton.—At Hampton, No. 2 primary bed started in the early part of 1899 with an estimated water capacity of approximately 43,500 gallons, and was found on February 3rd, 1903, to have a capacity of only 8,637 gallons. On September 23rd, 1904, after a fortnight's rest, its capacity had risen to 12,965 gallons.

A gain of capacity in contact beds, by giving them rest, has been commonly noticed ever since they were first brought into use by Mr. Dibdin. For some time the cause of the gain was assigned to the biological digestion of the suspended matter caught in the material of the filter. A part of the gain in capacity which takes place during rest is no doubt due directly to this cause; but we think that much is due indirectly to the digestion tending to make the organic matter in the bed of a more granular and less spongy character. The ultimate gain in capacity is due to the water being able to drain away. It was shown, by Colonel Harding and Mr. Harrison at Leeds, that the deposit in a primary contact bed which had caused that bed to lose capacity contained something like 90 per cent. of water.

It must be remembered, however, that the gain in capacity which results from the resting of a clogged bed is generally only of a temporary character, a short rest of, say, a fortnight, serving for little more than to shrivel up the spongy and gelatinous matter in the interspaces of the bed. In many cases it has been observed that such matter returns to its original spongy state soon after the bed has been restarted. If a bed could be rested for a very long time, the sewage matter would become permanently granular through oxidation; but this is not practicable on a large scale, and as it would possibly result in the bed losing its maturity, it is important not to allow a contact bed to become so seriously clogged as to necessitate a prolonged rest.

As we have already intimated, it is important that the drainage should be efficient. Unless a bed is so constructed as to allow of proper drainage it will inevitably suffer rapid loss of capacity. Moreover its oxidising power will be impaired.

(8) *Suspended Matter in Liquid.*

118. Where the greater part of the suspended matter in the incoming liquid is allowed to find its way into the body of the material, the loss of capacity tends to vary in direct proportion to the amount of suspended solids in the sewage or tank liquor which is being treated. If very fine material is used in a bed, or if a bed of medium sized material is coated with a layer of very fine material, a large proportion of the suspended matter is caught upon the surface.

There is a large amount of experience showing that primary contact beds lose capacity at a greater rate than secondary beds, and we think there can be no doubt that this is largely due to the fact that the primary bed usually receives considerably more suspended matter. At the same time the facts that the suspended matter in a primary bed effluent is of a somewhat different character to the suspended matter in a tank liquor or a crude sewage, and that there is less colloidal matter in a primary bed effluent, would, to a lesser extent, account for the difference.

119. The following table shows the loss of capacity, per million gallons of liquor treated, at places which have been under our own observation, where septic tank liquor was treated on *primary* contact beds of medium sized material :—

Place.	Suspended matter in the liquor treated. (Hourly samples taken in dry weather.)	Age of beds in months.	Average number of times beds were filled per day.	Estimate of total number of gallons treated.	Loss of capacity in gallons.	Rate of loss of capacity per million gallons.
Guildford - - -	15·9	46	2·0	223·8 millions	108,794	486 gallons
Exeter (Main Works)	12·5	37	1·62	2,056 millions	750,750	365 gallons
Andover - - -	11·1	38	1·2	96 millions	79,600	828 gallons
Exeter (Old Works) -	8·2	109	1·64	196·2 millions	39,670	202 gallons
Slaithwaite - -	7·1	84	2·0	226·2 millions	33,755	149 gallons

With the exception of Andover, the loss of capacity per million gallons was, approximately, in proportion to the amount of suspended matter put upon the beds. The high rate of loss of capacity at Andover is accounted for by the fact that the material in the beds disintegrated to such an extent as to cause the surface level to sink considerably.

120. In connection with this matter we may refer to our Accrington * experiment. In that experiment two pairs of contact beds were run side by side for rather more than a year, one pair receiving two fillings per day of septic tank liquor, and the other pair receiving four fillings per day of the same tank liquor diluted with an equal volume of water. Both beds, therefore, received equal aggregate amounts of suspended matter. The capacity measurements throughout this time were as follows :—

	Primary bed treating septic tank liquor undiluted.	Secondary bed treating septic tank liquor undiluted.	Primary bed treating septic tank liquor diluted.	Secondary bed treating septic tank liquor diluted.
	Gallons.	Gallons.	Gallons.	Gallons.
May 3rd, 1905 (before starting) -	1,170	1,035	1,185	1,070
October 25th, 1905 - - -	810	1,080	770	940
June 6th, 1906 - - - - -	735	1,030	780	950

During this period, therefore, the two primary beds (of coarse material) lost capacity at, approximately, the same rate, the loss (435 gallons) in the primary bed treating the one volume of undiluted tank liquor being slightly greater than the loss (405 gallons) in the primary

* *See* pp. 110-117 and also Appendix IV.

bed treating the two volumes of diluted tank liquor. Even this small difference is explained by the fact that rather more than the proper proportion of suspended matter was, on the average, washed out of this bed, as the primary bed treating diluted tank liquor was emptied twice as frequently as the other. The average suspended matter in the effluent from the primary bed treating the one volume of undiluted tank liquor during the period was 6·3, and in the effluent from the primary bed treating the two volumes of diluted tank liquor 3·6 parts per 100,000. As the two primary effluents were discharged on to the two secondary beds (of fine material), the effect of the suspended solids was shown in these also, the difference in rate of loss of capacity being still further accentuated there by the fact that the secondary bed treating diluted tank liquor, unlike the primary bed, retained rather more than its proper proportion of suspended matter. The suspended matter in the effluent from the secondary bed treating undiluted tank liquor averaged 4·2, and in the effluent from the secondary bed treating diluted tank liquor 1·7 parts per 100,000. It is obvious, therefore, that, at any rate, the greater part of the disproportionate loss of capacity in the secondary bed treating the two volumes of diluted tank liquor was due to the fact that this bed received rather more suspended matter than the other secondary bed, and also held rather more back.

In June, 1906, the method of working the beds was altered. One set of beds then received two fillings per day of septic tank liquor undiluted, and the other set two fillings per day of septic tank liquor diluted with an equal volume of town's water. The first pair therefore received twice as much organic impurity, *including twice as much suspended matter*, as the second.

As will be seen from the following capacity measurements, the primary beds receiving the undiluted tank liquor soon began to lose capacity.

——	Primary bed treating septic tank liquor undiluted.	Secondary bed treating septic tank liquor undiluted.	Primary bed treating septic tank liquor diluted.	Secondary bed treating septic tank liquor diluted.
	Gallons.	Gallons.	Gallons.	Gallons.
June 6th, 1906 - - -	735	1,030	780	950
February 18th, 1907 - -	640	970	750	890

During this second period of working, the primary bed receiving one volume of undiluted tank liquor lost 95 gallons of capacity, while the primary bed receiving one volume of diluted tank liquor lost only 30 gallons. The average quantities of suspended matter entering and leaving the two primary beds for the period were as follows :—

——	Primary bed receiving one volume of septic tank liquor undiluted.	Primary bed receiving one volume of septic tank liquor diluted
	Parts per 100,000.	Parts per 100,000.
Average quantity of suspended matter going on to bed -	14·1	7·3
Average quantity of suspended matter coming out of bed	7·7	3·7

It might have been expected that the loss of capacity in the secondary bed treating the diluted tank liquor would have been only half the loss of capacity in the secondary bed treating the undiluted tank liquor. It will be seen, however, that the loss of capacity in the secondary beds was the same in each case. The suspended solids in the effluent from the secondary bed treating the undiluted tank liquor averaged 5·0 parts per 100,000,

but the suspended solids in the effluent from the secondary bed treating the diluted tank liquor, so far as we could judge from the centrifuge figures (which, however, can only be taken as approximate), were about one-third of this, the actual figures being as follows :—

——	Secondary bed receiving one volume of septic tank liquor undiluted.	Secondary bed receiving one volume of septic tank liquor diluted.
	Parts per 100,000.	Parts per 100,000.
Average quantity of suspended matter going on to bed -	7·7	3·7
Average quantity of suspended matter coming out of bed	5·0	1·7 approx.

In both periods of working (May 3rd, 1905, to June 6th, 1906, and June 6th, 1906, to February 18th, 1907), the loss of capacity in every one of the four beds (primary and secondary) ran concurrently with the amount of suspended matter held back by the bed.

Campbell, 21665. Harrison, 22016. Valentine, 22462. Wike, 23571.

121. A contact bed loses capacity rapidly at first, and subsequently at a diminished rate. Evidence in regard to this was given by Mr. Campbell, of Huddersfield, Mr. Harrison, of Leeds, Mr. Valentine, of Oldham, and Mr. Wike, of Sheffield, and others.

At Huddersfield the period of rapid loss in the case of the primary bed was within the first five months, and in the case of the secondary bed within the first twelve months. At Leeds it seems to have been within the first nine or twelve months ; at Oldham within the first twelve months ; at Sheffield, for the primary contact bed, within the first six months, and for the secondary bed, within the first twelve months.

We may also refer to the experimental Roscoe beds at Manchester which, after losing capacity for some time, eventually reached an equilibrium, and from then onwards maintained a constant water capacity so long as the suspended matter accumulating on the surface was periodically removed. These beds were filled with chemically precipitated sewage, which usually contains less colloidal matter than settled sewage or septic tank liquor.

It does not appear that any rule can be deduced as to the length of the period during which capacity is lost rapidly. It would, no doubt, partly depend both upon the rate of filtration and upon the amount of suspended matter reaching the bed.

How to Diminish the Rate of Loss of Capacity.

122. The capacity of a contact bed is best maintained by :—

Preventing as far as possible the access of suspended or colloidal matter to the bed ;

Using materials which are not liable to disintegrate ;

Using for the body of the filter material of even size, and in the form of cubes or spheres rather than flakes.

Allowing thorough and efficient drainage ;

Not over-working the bed ;

Giving periodical rests ;

Filling and emptying the bed in such a way as not to disturb the material.

The access of suspended matter to a contact bed is, in most cases, the chief cause of loss of capacity, and no doubt the rate of loss can be greatly lessened by carefully eliminating the suspended solids from the sewage before filtration.

Some small experimental filters at Kingston, fed with precipitation liquor, which had been produced by the "A.B.C." process, maintained their capacity in a remarkable manner. By this process a tank liquor is obtained containing a very small amount of suspended solids.

Even the best known means for removing the suspended matter by preliminary treatment does not get rid of it entirely, and it is generally advisable to provide a layer of fine material in the upper few inches of the bed, so as to prevent, as far as possible, the suspended matter from gaining access to the body of the bed.

Experience may show that it is economical to adopt some intermediate method of removing suspended matter from tank liquors. At Birmingham, Dortmund tanks are used for this purpose, and at Leeds, Chester, Ilford, and Guildford, mechanical straining has been tried. The latter method, however—as carried out at those places—has not been satisfactory.

The question whether it is more economical frequently to wash or renew the material in contact beds, or to remove the greater portion of the suspended matters from the liquor before it is treated, and to wash the beds less frequently, depends primarily on local circumstances.

Of the preliminary processes for removing suspended matter from sewage, chemical precipitation followed by either quiescent or continuous flow settlement is undoubtedly the most efficient of those at present known; but it involves a larger annual cost in most cases than settlement by means of settling or septic tanks, and there is a larger quantity of sludge to be dealt with.

Washing of Filtering Material.

123. The evidence shows that in many cases it is practicable and economical to wash filtering material which has become clogged. The cost varies according to local circumstances, and the following instances may be cited.

At *Burnley*, the material of several clogged beds was washed by means of an inclined rotary screen, 10 feet by 4 feet, fixed at a suitable elevation and so constructed as to be easily capable of removal from bed to bed as required. The arrangement admitted of washing, grading, and screening the material (clinker): the washing was effected by the tank effluent: and the power was supplied by a portable engine. Pickles and Ross, 20785.

The cost of these operations was at the rate of 1s. per cube yard of material, which covered excavating, packing troughs, wheeling, and screening and washing not only the material excavated but also the additional material required to take the place of the old material rejected (about 10 per cent.) and filling it into the bed.

At *Leeds*, Mr. Harrison, the chemist to the Corporation, washed 1,020 cubic yards of material, by hand labour with screens and a heavy flow of water, at a cost of 2s. 5d. per cube yard. Harrison, 22017.

At *Manchester*, the washing of filtering material has been done on a very large scale, and is carried on continuously. The method employed is to pass the material from a sump to a jigging screen of $\frac{1}{4}$-inch mesh, over which are fixed a series of horizontal water sprayers. The material rejected by this screen is further graded by passing over a fixed 2-inch mesh screen. The material which passes through the $\frac{1}{4}$-inch screen falls on to an inclined fixed screen of $\frac{1}{8}$-inch mesh. All material above $\frac{1}{4}$-inch is replaced in the primary filters; that between $\frac{1}{4}$-inch and $\frac{1}{8}$-inch will be used for the surface of the secondary contact beds, when these are constructed. Settled sewage is the liquid used in the washing.

The total cost of removing, washing, screening and replacing in beds and making up to original level with new material at Manchester, is 1s. 6d. per cube yard. This does not include cost of washing machinery.

At *Birmingham*, 20,000 cubic yards of material were dealt with in the following manner: the material was dug out of the beds by manual labour and conveyed in tip wagons to a high platform by an electrically-driven winch; it was then passed through revolving screens and simultaneously washed with sewage.

The cost of removing, washing, screening and replacing material in the beds was at the rate of 11d. per cube yard. With the additional material required to make up to original level of bed, the total cost was 2s. 2½d. per cube yard. This does not include the cost of the washing plant.

At the *Beddington* and *South Norwood* sewage works of the Corporation of Croydon, filtering material has been washed on a large scale. The work was done by hand labour, and the cost of washing and replacing the material in the beds was approximately 1s. 2½d. per cube yard at Beddington, and 1s. 6d. per cube yard at South Norwood.

At *Andover*, the cost of washing and replacing material by hand labour, with a special apparatus devised by Mr. R. W. Knapp, the surveyor, was about 2s. 4d. per cube yard. This covered the initial cost of the washing apparatus.

At *Hampton*, washing is effected by means of a machine driven by compressed air. The cost of removing old material, screening, washing and replacing in bed, and providing new material to make up deficiency (25 per cent.), is 1s. 9¾d. per cube yard.

Campbell, 21852. At *Huddersfield*, the borough engineer found that the cost of washing material was not less than 4s. 6d. per cube yard. No information was given as to the method employed.

124. The cost of washing, etc., at the several places mentioned (except Huddersfield) is summarised in the following tables:—

MATERIAL WASHED BY MACHINERY.

Name.	Nature of liquid treated by beds.	Average amount of suspended matter in liquid going on to beds (parts per 100,000).	Time beds had been in use.	Nature and size of material.	Quantity of material dealt with (cube yards).	Cost per cube yard of washing operations, including making beds up to original level with new material, but excluding cost of washing plant and maintenance charges on same.	Cost per acre, 3 feet deep, of washing operations, including making beds up to original level, with new material, but excluding cost of washing plant and maintenance charges on same.	Percentage of original material replaced in bed.	Cost per cube yard of new material.	Remarks.
						s. *d.*	£ *s.* *d.*			
Burnley - -	Septic tank liquor	5 to 6	3½ years	Clinkers (⅛″ to ½″)	3,350	1 0	242 0 0	60 per cent.	—	
Manchester -	Septic tank liquor	5 to 6	4 to 5 „	Clinkers (medium to coarse)	A very large quantity	1 6[b]	363 0 0	70 per cent. to 75 per cent.	½″ to 2″—2*s.* 6*d.* to 3*s.*; over 2″ 3*s.* to 3*s.* 6*d.*[a]	[a]Delivered in the beds. [b]Final disposal of rejected material not included in this figure.

Andover - -	„ „	11·10[e]	4 „	Clinker (½″ size free from dust)	490	2 4[e]	564 0 0[d]	—	—	[d]Including cost of plant.
Leeds - - -	—	—	—	—	1,020	2 5	584 0 0	—	—	[e]Based on the three sets of average samples, taken October, 1904.
Averages - -	—	—	About 4 years	—	—	2 0	484 12 0	—	—	

It should be added that washed material has an enhanced value for filtration purposes, due in great measure to the fact that the softer and more friable portions of the original material, which have become broken down, are eliminated in process of washing.

125. We may mention here that other plans for restoring contact beds which have become clogged have come under our observation at Hartley Wintney, Hendon, and Oswestry.

At *Hartley Wintney* the contact bed material (gas works clinker) was simply turned over. The amount dealt with was 679 cube yards; one man was employed; and the cost amounted to only 5½d. per cube yard.

The beds had been in use about four and a half years when the material was turned over.

The increase in capacity due to this process was, however, quickly lost again.

At *Hendon*, the ballast on the percolating beds was reburned. The cost amounted to 3s. 6d. per cube yard; but this covered the sifting out of the small material, wheeling out the fine stuff and spreading it, and relaying drains, etc. The beds had been in use for sixteen years.

At *Oswestry*, the old material of the beds was so disintegrated as to render washing impracticable, and there was sufficient new material (screened cinders) lying on the site. The old material (cinders) was therefore discarded and the beds filled with new material. The quantity dealt with was 1,550 cube yards, and cost of removing and renewal amounted to 2s. 7½d. per cube yard. The beds had been in use for about four years.

Filtering Material in Contact Beds.

126. The materials in general use for contact beds are clinker and coke, and experience of other materials is not very great.

With percolating filters, however, many different materials have been used, and although the actual working of percolating filters is different from that of contact beds, the results are, to a large extent, applicable. At York, a quantitative experiment with septic tank liquor was made by us on a circular percolating filter 7 feet 8 inches deep and constructed in four segments—one of clinker, one of coke, one of slag, and one of broken brick—the material in each case being broken and riddled as nearly as possible to the same size; the bulk of the clinker was, however, distinctly smaller than the other three materials. The results showed that the best effluent was obtained from the clinker segment, that the coke and slag segments gave very similar effluents, but not quite so good as the effluent from the clinker segment, and that the effluent from the broken brick segment was lowest in the scale of purity. All four effluents were of good quality.

Watson 25004. At Hendon the late Colonel Ducat obtained a better effluent from clinker in a percolating filter 8 feet deep than from pebbles in the same bed. At Birmingham Mr. J. D. Watson found that for percolating filters gravel has too smooth a surface. Dr. George Reid also stated in evidence that "any hard, non-friable material of irregular shape and not too smooth a surface, and one which is not liable to disintegrate is satisfactory as a

Fowler, 22794. filtering medium for percolating filters."

The experience at Manchester, with regard to contact beds, has been that hard furnace clinker is the best material, being vesicular and yet permanent. Dr. Fowler, however, expressed the opinion that broken Staffordshire bricks, saggars and gravel, if properly sized, should do equally well.

It will be seen from the evidence that many witnesses have stated that substances like gravel, flints, or broken granite, are suitable as a filtering medium, but that, in most cases, tney have expressed a decided preference for the use of those materials which present the roughest and most irregular surfaces, such as clinker, coke, and saggars.

So far as our own experience goes, we should prefer, as a general rule, to use coke or good clinker in a contact bed in preference to other materials.* It is true that there is some evidence to the effect that rather better effluents can be obtained from contact beds of coke than from contact beds of clinker, but we think that this advantage is balanced by the tendency of the lighter material, coke, to shift slightly every time the bed is filled, and therefore to be more liable to disintegration.

* Broken "saggars" might be equally good, but we have had no experience of this material in contact beds.

In the choice of a filtering medium local circumstances must, of course, be taken into account. For example, there may be places at which a somewhat inferior material may be obtained at a very low price, and where it would be cheaper to renew the beds more frequently, or to provide a larger area of beds, than to pay the higher price for better material.

Probably most materials will purify sewage, but a larger quantity of smooth than of vesicular material would be required to produce equal purification.

127. Mr. W. J. Dibdin has lately advocated the use of large slabs of slate in primary contact beds, the horizontal layers of slate being separated from one another by cross pieces. He claims that crude sewage can be purified to a considerable extent in such beds, and that the sludge which accumulates in them can be periodically flushed out with water. Up to the present time we have had no experience of primary contact beds constructed in this way, beyond a single visit to Devizes where such beds were in use for the treatment of screened sewage. As a result of our inspection of the beds at Devizes, we came to the tentative conclusion that primary beds containing large slabs of slate must be regarded more as preliminary settling or septic tanks than as contact beds. As to the feasibility of washing such beds out, or as to the amount of digestion of sludge which takes place in them, we are unable to express an opinion.

Size of Material.

128. The smaller the size of material used in a contact bed the greater is the internal surface area exposed, and consequently the more intimate is the contact of the liquid with the material, the greater the purification, and the more efficient the arrest of the suspended and colloidal matter.*

The efficiency of a contact bed, however, depends very largely upon the admission of air to all parts of the filter during the time the bed is resting empty. Thorough and rapid drainage is therefore of the utmost importance.

For this reason, it is important that the material in a contact bed should not be *too* small, especially if the liquid to be treated contains an appreciable quantity of suspended matter, as some of this suspended matter will undoubtedly find its way into the interstitial spaces and prevent proper drainage of the bed. This was found to be the case with the fine beds at Devizes and Hampton.

At Devizes the contact beds were composed of very fine clinker broken to a diameter from $\frac{1}{4}$-inch downwards and including dust. Shortly after the beds were brought into operation, working at a rate of three fillings per day, it was found, on digging down into them, that the liquid of one filling had not drained away from the beds when the time for the next filling arrived. On examination it appeared that, although there was not actually a large quantity of sewage solids admixed with the filtering material, enough was present to bind the whole together, so that the bed drained away very slowly.

At Hampton the tertiary contact beds were composed of furnace clinker of $\frac{1}{4}$-inch or less, including dust, and after five years' work the material had settled into an almost solid mass, and the beds could only be filled with difficulty. The material, when turned out, presented a very similar appearance to that at Devizes, being closely bound together, although mixed with only a small proportion of sewage suspended matter.

129. If the liquid to be treated contained no suspended or colloidal matter, material as fine as medium sand would probably give the best results ; but if crude sewage were to be put upon this sand, the surface would become so clogged with sewage sludge in two or three fillings that the bed would be practically useless. The top layer would then have to be removed, or the bed would have to be rested until the sludge upon the surface had dried sufficiently to be raked off. Even if the top sand were constantly removed and replaced, it would be found, as at Hampton and Devizes, that some particles of suspended matter would penetrate into the interior of the bed, and that eventually the drainage of the bed would become defective.

---

* Note.—See Biltz and Kröhnke, Berichte, vol. xxxvii., p. 1745 ; Fowler and Ardern, J. Soc. Chem. Ind., vol. xxiv., p. 483 (1905) ; Jones and Travis, Proc. Inst. C.E., vol. clxiv., paper 3599, p. 32 (Jan. 1906) ; O'Shaughnessy and Kinnersley, J. Soc. Chem. Ind., vol. xxv. (April, 1906); Johnston, J. Roy. San. Inst., vol. xxvii., p. 10 (1906).

In deciding upon the size of the material to be used, the amount of suspended matter in the liquid to be treated, must be considered. As a general rule, the greater the amount of suspended matter in the liquid the larger the material should be.

With a crude sewage containing 40 parts per 100,000 of suspended matter, the material will probably have to be from 3 inches upwards in diameter, and even then sludge will accumulate on the top.

With a septic tank liquor containing 8 to 10 parts per 100,000 of suspended matter, material of a diameter from $\frac{3}{8}$ to $\frac{5}{8}$ of an inch may probably be used effectively; while with a good precipitation liquor containing from 1 to 3 parts of suspended matter, the best results will probably be obtained from material as fine as $\frac{1}{4}$-inch diameter.

130. It is, however, impossible to make any but the most general statement as to the most suitable size of material for contact beds, as, in some cases, there may be special circumstances which affect the question, such as the character of the suspended matters, or the smoothness of the filtering material. The sizes we have suggested are based on the evidence which we have received and also on our experience of contact beds at the places named in the following statement :—

	Suspended matter in the liquor treated (approximate figures).	Nature of material.	Size of the material in the contact beds.
Crude Sewage.	Parts per 100,000.		
Hampton	48·5	Clinker.	Above 4″ diameter.
Leeds	35·0	Clinker and coke.	Above 3″ diameter.
Newton-le-Willows	30·0	Clinker.	Top 18″—$\frac{1}{2}$″ to $\frac{1}{4}$″ diameter. Body of filter, 2″ to 1$\frac{1}{2}$″ diameter.
Withnell	20·0	Clinker.	1″ to 1$\frac{1}{2}$″ diameter.
Maidstone	14·0	Clinker.	Above $\frac{3}{4}$″ diameter.
Settled Sewage.			
Oswestry	About 20.	House coke.	1$\frac{1}{2}$″ to $\frac{1}{2}$″ diameter.
Halton	11·0	Clinker and pebbles.	1″ to 2″ diameter.
Septic Tank Liquor.			
Leeds	18·0	Clinker.	$\frac{5}{8}$″ to $\frac{3}{8}$″ diameter.
Guildford	16·0	Burnt ballast.	$\frac{1}{2}$″ to 3″ diameter.
Hartley Wintney	15·0	Clinker.	$\frac{1}{2}$″ to $\frac{1}{8}$″ diameter.
Exeter (Main)	About 14.	Clinker.	$\frac{1}{2}$″ to 1″ diameter.
Andover	12·0	Clinker.	$\frac{1}{8}$″ to $\frac{1}{2}$″ diameter.
Exeter (St. Leonards).	8·5	Clinker and coke.	$\frac{1}{2}$″ diameter.
Slaithwaite	8·0	Clinker.	Top foot—$\frac{3}{8}$″ to $\frac{1}{3}$″ diameter. Body of filter, $\frac{3}{8}$″ to 1″ diameter.

Grading of Material.

131. From our own observations, and from the evidence, we are of opinion that, as regards the bulk of the material in the bed, grading is not necessary, and that much labour and expense have sometimes been incurred, to very little purpose, in too great a refinement of grading. A certain amount of grading is, however, always necessary. Over the drains of the beds, for instance, material of fairly large size must be laid in order to prevent choking. Again, in order to preserve the life of a contact bed, it is advisable to retain as much as possible of the suspended matter upon the surface of the material, and this seems to be best effected by using fine material for the top 6 inches or so.

We may refer particularly to the evidence on this question which was given by Mr. D. Cameron (2091); Mr. Baldwin Latham (4505); Colonel Harding (7165–6); Dr. P. F. Frankland (9985–6); Mr. Bolton (21145); Mr. J. Kershaw (21464); Mr. Campbell (21655); Mr. Harrison (22008); Dr. Fowler (22795); Mr. Wike (23652); Mr. Wilkinson (24286); Messrs. Willcox and Raikes (26182).

Amount of Sewage which can be Treated on Contact Beds.

132. The amount of sewage which can be treated on contact beds chiefly depends on the strength of the sewage, on the quality of effluent which it is required to produce, on the amount of suspended solids in the sewage, and on the size of the filtering material. The question is dealt with in the section headed "General Conclusions as to the Working Power of Different Types of Filter," p. 117.

PERCOLATING FILTERS.

Depth of Percolating Filters.

133. The question of the depth of percolating filters is one of far greater complexity than at first sight appears. At most places the depth has usually been determined by the levels. If plenty of fall has been available, deep filters have been constructed, while at places with little fall, the material has usually been laid out in the form of a shallow filter. In other words percolating filters have usually been constructed as deep as levels would allow. In some cases the advantage of deep filters over shallow filters has even been considered sufficient to justify the adoption of pumping.

It has thus been generally accepted that, in the case of percolating filters, the deeper the material the better the result obtained. That there were good grounds for this conclusion will be seen from the following evidence.

At Accrington, in 1897, Mr. C. J. Whittaker, experimenting upon the depth of filtering material necessary for the purification of open septic tank liquor by means of the Whittaker and Bryant percolating filters, compared the results obtained from filters 6 feet and 9 feet deep, both constructed of the same coarse material and both receiving the same quantity of tank liquor *per square yard.* Mr. Whittaker found that the 9 foot bed gave better purification and higher nitrification than the 6 foot bed.

At Leeds, in the year 1900, Colonel T. W. Harding and Mr. W. H. Harrison, in their experiments upon the continuous filtration of crude sewage, touched upon the same point. In one of these experiments, which lasted for six months, Leeds crude sewage was allowed to trickle continuously through three filters one after another, one object of the experiments being to ascertain the purifying effect of each separate filter. The filters were 3′ 6″, 2′ 6″ and 2′ 6″ deep respectively, so that the total depth of the material, which consisted of coarse coke, was 8′ 6″. The average analyses of the effluents from each filter, from March to June, 1900, were as follows :—

Grains per gallon.

———	Crude Screened Sewage.	First Filter 3′ 6″ deep.	Second Filter 2′ 6″ deep.	Third Filter 2′ 6″ deep.
Free Ammonia - - -	2·36	1·58	1·15	0·83
Albuminoid Ammonia - -	1·04	0·59	0·43	0·29
Oxygen absorbed from permanganate in 4 hours.	8·90	4·37	2·78	1·93
Nitrogen as nitrates - -	—	—	—	0·14
Total solids - - - -	123·2	87·6	74·0	7·17
Suspended solids - - -	44·2	19·2	7·9	7·7

Another experiment was made by Mr. Carter Bell, at Salford, during the years 1900 and 1901, on the depth of medium-sized material necessary for the purification of Salford precipitation liquor. In this experiment three percolating filters 8 feet, 5 feet, and 3 feet deep, all constructed of medium-sized clinker, received precipitation liquor at the same rate *per square yard.* Typical analyses of the effluent are given by Mr. Carter Bell as follows :—

Grains per gallon.

	Shallow filter 3 feet deep.	Medium filter 5 feet deep.	Deep filter 8 feet deep.
Free Ammonia - - - - - - - -	2·6	2·4	2·2
Albuminoid Ammonia - - - - -	0·20	0·18	0·14
Oxygen absorbed from permanganate in 4 hours -	1·1	0·8	0·5
Nitrogen as nitrates - - - - - -	0·84	1·10	1·30
Total solids - - - - - - - -	65·0	66 0	65·0
Koch's gelatine and incubation test - - - -	Fairly satisfactory.	Satisfactory.	Very satisfactory.

At Horfield, Mr. F. W. Stoddart, experimenting with two filters of coarse clinker, one 7′ 6″ deep and the other 3′ deep, came to the conclusion that with an equal flow *per square yard* the deep filter gave the better results.

134. There were no doubt many other experiments of the same kind, showing that, when treating the same amount of sewage per square yard, the deeper the filter the greater is the purification effected. These experiments, however, do not show whether it is better to arrange a *given* quantity of material in the form of a deep or of a shallow percolating filter, and so far as we are aware no systematic experiments on the treatment of sewage or sewage liquor upon filters of different depths at equal rates *per cube yard*, instead of *per square yard*, were carried out until our observations were begun at Horfield and Ilford.

Horfield Experiments.

135. At Horfield, experiments were made in the years 1904–5, upon two filters of coarse clinker, one 7′ 5″ deep and the other 3′ deep, upon each of which quantities of Horfield precipitation liquor were treated at approximately the same rate *per cube yard* per day for ten months. Both filters were fed by means of Stoddart trays. The deep filter had a cubic content of 284 cube yards and the shallow filter of 27·56 cube yards.

The results showed that there was little to choose between the two effluents, though on the whole the effluent from the deep filter was slightly the better. At the same time, though the experiments showed that a coarse shallow filter (3 feet in depth) can quite well be made to give satisfactory results in the treatment of a precipitation liquor like that at Horfield, they also indicated that with coarse material, where the levels allow of it, a deep filter is on the whole preferable to a shallow one, especially where a strong liquor is being dealt with, since faults of distribution are toned down more.

Ilford Experiments.

136. At Ilford, a similar experiment with two very small percolating filters fed by means of Stoddart trays was made in 1903–4. The filters had the following dimensions :

Deep filter 12 feet by 9 feet and 6 feet deep.

Shallow filter 12 feet by 9 feet and 3 feet deep.

The material used was coke, from $1\frac{1}{2}$″ to 3″ in diameter. Both filters were fed with septic tank liquor at the rate of 125 gallons per cube yard per day. The effluents obtained from both filters were usually non-putrescible, though not of high quality, the deep filter effluent being rather the better of the two.

In order to improve the distribution, the filters were to some extent remodelled in the early part of 1907 ; that is to say, the distributors were levelled and the upper layers of coarse coke were replaced by finer coke ($\frac{1}{4}$″ to $\frac{3}{8}$″ diameter) to the depth of six inches on the deep filter and 3 inches on the shallow filter. Immediately below these fine layers, there were four inches in the deep filter, and two inches in the shallow filter, of medium sized coke.

From April 15th to June 28th, 1907, the filters were brought to maturity with gradually increasing quantities of septic tank liquor. During the time of the actual experiment, which lasted from June 1st, 1907 to January 20th, 1908, the quantities of septic tank liquor treated were as follows :—

On the deep filter (12′ × 9′ × 6′)—3,000 gallons, or 125 gallons per cube yard per 24 hours.

On the shallow filter (12′ × 9′ × 3′).—1,500 gallons, or 125 gallons per cube yard per 24 hours.

Between these dates, ten corresponding samples of septic tank liquor and of both filter effluents were drawn. The average figures for the analysis of the septic tank liquor were as follows :—

Septic Tank Liquor.

Parts per 100,000.

——	Maximum and minimum figures.	Average figures.	Number of estimations.
Total nitrogen	4·95 – 8·40	6·75	10
Oxygen absorbed from permanganate at once	1·17 – 4·39	3·34	10
Oxygen absorbed from permanganate in four hours	5·54 – 8·64	7·43	10
Suspended solids	5·3 – 9·2	6·9	10
Volatile matter in suspended solids	4·2 – 6·9	5·4	10

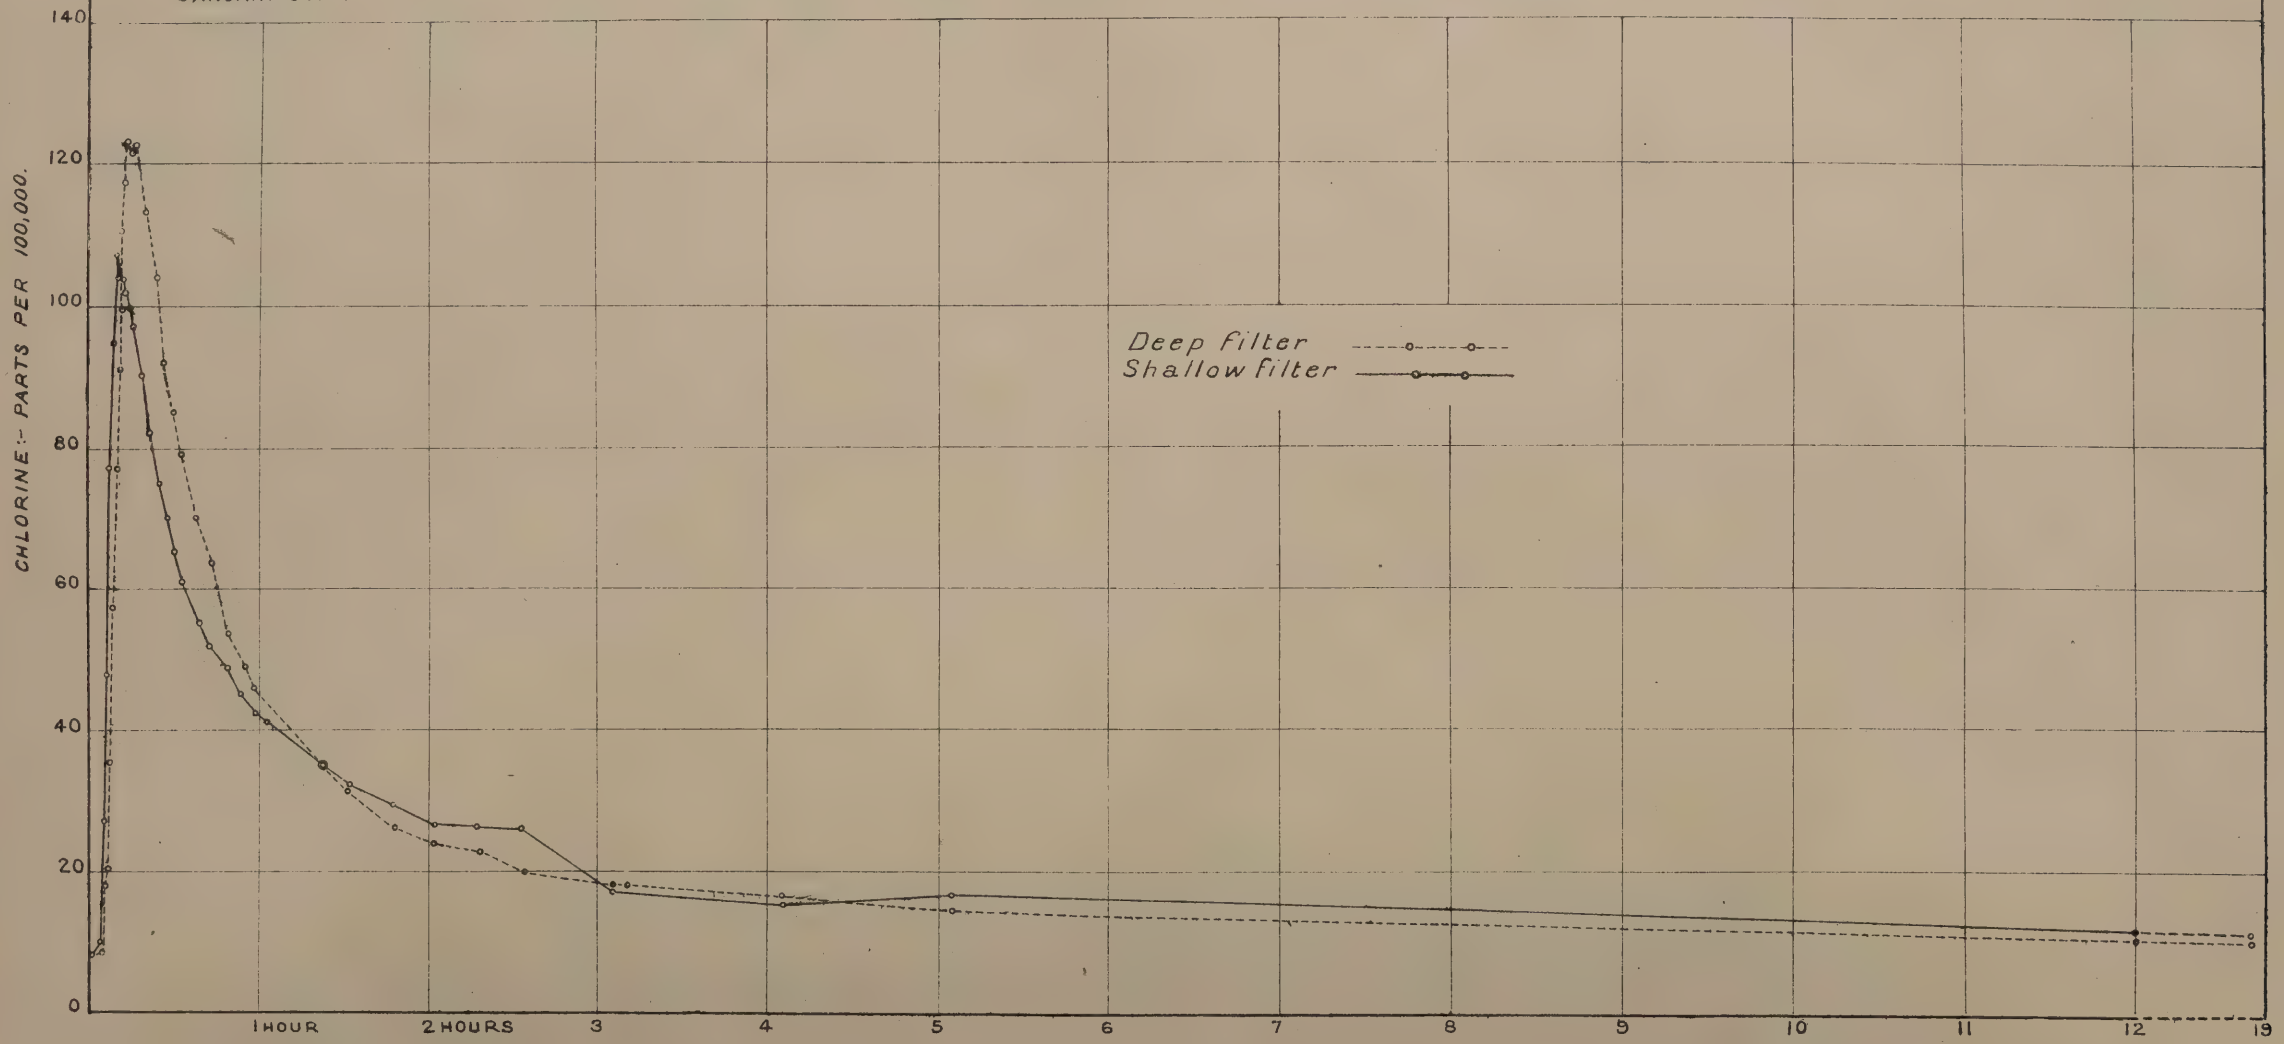
The calculated strength* of this liquor is 78·7, or after allowing for the abnormal ratio of the figure for oxygen absorbed at once to the figure for oxygen absorbed in four hours, 67·6.

The following table shows the average figures of the analysis of both effluents, with and without suspended matter :—

Effluents.

Parts per 100,000.

——	Analysis of sample containing suspended solids.		Analysis of sample after filtration through paper.	
——	Deep filter effluent.	Shallow filter effluent.	Deep filter effluent.	Shallow filter effluent.
Number of samples included in the average	10	10	7	7
Ammoniacal Nitrogen	2·92	3·55	2·93	3·54
Albuminoid Nitrogen	0·47	0·47	0·25	0·28
Total Organic Nitrogen	0·79	0·84	—	—
Nitrous Nitrogen	0·13	0·15	0·13	0·15
Nitric Nitrogen	1·94	1·35	1·94	1·35
Total Nitrogen	5·76	5·64	—	—
Oxygen absorbed at once	0·86	0·86	0·49	0·58
Oxygen absorbed in 4 hours	3·12	3·09	1·71	2·11
Incubator test (Scudder)	All passed.	8 passed, 2 failed	—	—
Incubator test (by smell)	All passed.	9 passed, 1 failed		
Dissolved Oxygen taken up in 48 hours	2·05	1·74	0·65	0·79
Dissolved Oxygen taken up in 5 days	6·62	6·49	1·49	1·90
Solids in suspension	6·40	5·10	—	—
Volatile matter in solids	4·60	3·80	—	—
Solids by Centrifuge (Vols.)	73·0	60·2	—	—



Apart from suspended solids, both effluents were of moderate quality, that from the deep filter being slightly better than that from the shallow filter as regards ammoniacal nitrogen and nitric nitrogen, the figures otherwise being very much alike.

* Strength means the number of parts by weight of oxygen required to oxidise 100,000 parts, arrived at on the basis of the formulæ suggested by Dr. McGowan—*see* p. 16 of this Report, and Dr. McGowan's Memorandum in Appendix IV.

DIAGRAM 1.

CURVES SHEWING THE RATES OF FILTRATION THROUGH TWO COARSE PERCOLATING FILTERS OF DIFFERENT DEPTHS AT ILFORD, AS TESTED QUANTITIVELY WITH A SOLUTION OF SALT.

(EACH SMALL CIRCLE REPRESENTS A CHLORINE ESTIMATION.)

Weller & Graham, Ltd Litho, London

The following table showing the percentage purification obtained on the tank liquor, calculated in various ways, brings out the similarity :—

	Deep filter.	Shallow filter.
Calculated percentage purification on atmospheric oxygen used up (strength of septic tank liquor taken at 78·7). - - - -	74·6	71·8
*Units of purification on this basis (including suspended solids) -	7,339	7,063
Calculated percentage purification on atmospheric oxygen used up (strength of septic tank liquor taken at 67·6) - - - -	70·4	67·2
*Units of purification on this basis (including suspended solids) -	5,949	5,678
Calculated percentage purification, leaving out suspended solids (strength of septic tank liquor 78·7) - - - - - -	86·3	81·4
Calculated percentage purification, leaving out suspended solids (strength of septic tank liquor 67·6) - - - - - -	84·0	78·4

A little more work, *i.e.*, oxidation, was thus obtained from the deep filter per cube yard than from the shallow filter, but the difference was only slight, such as might be accounted for by the fact that imperfect distribution is more liable to affect the purification in a shallow filter than in a deep filter.

137. *For practical purposes we think the conclusion is justified that, within somewhat wide limits of depth, and given ample aeration and good distribution, the same amount of work can be got out of a cube yard of coarse material whether it is arranged in the form of a deep or of a shallow percolating filter.*

Rate of flow through Ilford filters.

138. With a view to ascertaining the relative rates of flow through the two filters the following experiment was made.

On January 9th, 1908, a strong solution of common salt was added to the septic tank liquor as it passed on to the two filters, samples of the effluent being taken at short intervals until almost all the salt had worked through the filters, a period in this case of about 19 hours.

The quantity of chlorine was then estimated in each sample.

It cannot be taken for granted that the passage of a solution of common salt through a filter is exactly similar to the passage of sewage impurity which is partly in true solution, partly colloidal, and partly in suspension. As sewage impurity passes through a filter it undergoes change, whereas the passage of a solution of common salt may be regarded for practical purposes as merely physical ; further, one may reasonably assume that sewage impurities are held up in the filter for a longer period of time.

The figures for the two filters were nearly alike throughout the experiment, but during the first hour a rather greater proportion of salt came through the deep filter, although, at the very beginning, the salt issued more quickly from the shallow filter. The figures are plotted out on Diagram I.

These experiments suggest that, given good distribution and ample aeration the extent of the purification effected by a percolating filter depends upon the length of time during which the liquor is in contact with the material, or, perhaps more correctly, upon the proportion of highly purified sewage in the effluent (*i.e.*, sewage which has taken hours to pass through the filter) to the proportion of sewage which has passed through more rapidly by following a much less circuitous route.

The three important factors which govern the rate of percolation are :—

(1) The kind of material, *i.e.*, whether the surface is rough or smooth ;

(2) The size of the material ; and

(3) The state of the filter as regards the bacteria and growths attached to the material, and also as regards worms, larvæ, etc.

* As to the meaning of the term "units of purification" *see* p. 107 of this Report.

Influence of the Nature of the Filtering Material.

139. We may refer to three experiments relating to the purification effected on the same sewage liquor by different filtering materials, all graded to be as nearly as possible of the same size.

In 1903, a circular filter, consisting of four kinds of material arranged in segments entirely cut off from each other by partition walls, was constructed by Mr. A. Creer at the York Sewage Works. The particulars of this filter, which was started on April 29th, 1903, were as follows :—

Diameter - - - - - - 100 feet.
Depth of material - - - - - 7 feet 8 inches.

Materials.

First Segment - - - - - 1,492 cube yards.
Clinker - - - - - $1\frac{1}{2}$ ins. to $3\frac{1}{2}$ ins. diameter.
Second Segment - - - - 312 cube yards.
Broken brick - - - - $1\frac{1}{2}$ ins. to $3\frac{1}{2}$ ins. diameter.
Third Segment - - - - 189 cube yards.
Blast furnace slag - - $1\frac{1}{2}$ ins. to $3\frac{1}{2}$ ins. diameter.
Fourth Segment - - - - 189 cube yards.
Gas coke- - - - - $1\frac{1}{2}$ ins. to $3\frac{1}{2}$ ins. diameter.

The filter was fed with septic tank liquor by a continuously revolving sprinkler, working automatically, and the rate of filtration on all four sections was approximately 360 gallons per square yard, or 140 gallons per cube yard, per day.

In June, 1904, we drew hourly samples of the effluent from each of the four segments over three complete days, the twenty-four samples from each segment being in each instance made up into a single sample for each complete day. As the three twenty-four hours' samples from each segment were very near to one another in chemical composition, only the average figures for each complete set of three days need be given here :—

Parts per 100,000.	Clinker.	Coke.	Slag.	Broken brick.
Ammoniacal Nitrogen - - - - - -	0·01	0·06	0·05	0·21
Albuminoid Nitrogen - - - - - -	0·10	0·10	0·12	0·15
Oxidized Nitrogen - - - - - -	2·90	2·47 approx.	2·32 approx.	2·48
Total Nitrogen - - - - - - -	3·18	2·95	2·72	2·88
"Oxygen absorbed" at 27°C. (80°F.) - *at once.*	0·38	0·49	0·63	0·63
„ „ „ - *in 4 hours.*	1·46	1·27	1.48	2·23
Dissolved Oxygen taken up in 24 hours at about 18°C. - - - - - - - - -	0·09	0·19	0.24	0·37
Dissolved Oxygen, in c.c. per litre - - -	0·65	1·32	1·72	2·57
Solids in suspension - - - - - -	2 15	1·22	1·73	2·00
Solids by Centrifuge (Vols.) - - - -	33·5	24·4	20·5	30·0
Ratio of Solids in suspension to Centrifuge solids-	1 : 15·6	1 : 20·4	1 : 17·3	1 : 15·0
Incubator Test (Scudder) - - - - -	All passed.	All passed.	All passed.	All passed.
„ „ (by smell) - - - - -	All passed.	All passed.	All passed.	All passed.
Smell when analysed - - - - - -	All good.	All good.	All good.	All good.

All these effluents were very good. It will be seen, however, that if we differentiate between them, the following is the order of merit for the different materials :—

(1) Clinker.
(2) Coke.
(3) Slag.
(4) Broken brick.

Between Nos. 2 and 3, the coke and the slag filter effluents, there is really no difference.

The foregoing experiment was made between June 27th and 30th, 1904, and we thought it well to test shortly afterwards—on July 19th—the comparative rates at which liquid coloured by fluorescine came through the different segments. The filtrates showed :—

	(*a*) Weak colour.	(*b*) Strong colour.
	Minutes.	Minutes.
1. Clinker	6	12
2. Coke	5	8
3. Slag*	8	9
4. Broken brick	2	2½

The order of the rate of percolation, as measured in this way, was thus the same as that of the purity of the effluent. Although the different filtering materials were all broken to be of the same size, the clinker was in reality somewhat smaller than the other three.

These experiments tend to confirm the view that the extent of the purification effected by a percolating filter depends upon the length of time taken by the sewage to pass through the filtering material, assuming always that the filter is properly aerated. Having regard to the vesicular nature of the clinker we should expect it to retard the passage of the sewage more than the broken brick, and hence to give a better effluent. The analytical results show that this was the case.

In his experiments at Hendon upon the filtration of crude sewage through medium-sized material, the late Colonel Ducat compared the results obtained from filters constructed of small pebbles and of clinker, both material being of the same size. The length of time taken by the sewage in passing through the clinker was, no doubt, greater than that taken by its passage through the pebbles, and the analytical results showed that better purification was obtained from the filter which was made of clinker.

In a laboratory experiment which was made by us at Leeds in the year 1900, we found that, using large smooth water-washed stones as the material in a filter five feet deep and one foot in diameter, and treating Leeds septic tank liquor at an approximate rate of about 70 gallons per cube yard per day, only traces of oxidised nitrogen appeared in the effluent after three or four months' working. Nitric nitrogen appeared in the effluents from the Whittaker filters at Leeds in a much shorter time than this. These latter filters were constructed of coarse coke or clinker and were fed with septic tank liquor at about the same rate, *i.e.*, 70 gallons per cube yard per day.

140. The results of these experiments may be summarised as follows :—

(1) Better results can be obtained per unit volume from a material with a rough surface than from a material with a smooth surface ; and

(2) The extent of the purification effected by a percolating filter varies with the average length of time taken by the sewage to pass through the filtering material, assuming that proper aeration of the filter is maintained.

Influence of the Size of the Material.

141. Although the experiments which we carried out at Ilford and Horfield showed that, with filters of coarse material, and given good distribution and ample aeration, a cube yard of filtering material will produce very similar results whether it is arranged in the form of a deep or of a shallow filter, it does not follow that this conclusion would apply to filters of medium-sized and fine material.

There are in reality three distinct classes of percolating filter in use for the purification of sewage or sewage liquors, viz. :—

(1) Percolating filters constructed of material coarse enough (say, over 2½″ in diameter) not only to give free access of air to its interior but also to allow the suspended matter in the liquid free passage through the whole depth of the filter. This is the class of filter to which the Ilford and Horfield experiments related.

* The amount of effluent coming from the slag segment was very small, owing to a strong wind on that side of the filter. The result for this section may therefore be of less value than would otherwise have been the case.

(2) Percolating filters constructed of medium-sized material (say, $\frac{1}{2}''$ in diameter), which temporarily retards the passage of suspended matter through the filter, while allowing free access of air to the interior.

(3) Percolating filters constructed of very fine material.

Percolating Filters Constructed of Medium-Sized Material.

142. In filters constructed of medium-sized material the suspended solids are arrested and held for some time in the upper layers of the material, and this part of the filter therefore receives a larger proportion of oxidizable suspended matter than the middle or lower parts. Where much suspended matter has to be dealt with, such filters tend to become choked in the uppermost few inches of the material, and to prevent the proper distribution of the liquid over the bed. In a filter of this kind, air is probably carried into the interior from the top downwards by the fall of the sewage liquor upon the material. There are many examples of filters of this class where the material is held in position by solid walls and where air could only gain access to the filter either through the outlet valves connecting to the drains or through the surface of the material. Colonel Harding and Mr. Harrison, at Leeds, showed clearly that after serious ponding took place on the surface of a filter of medium-sized material, although provided with perforated walls which would allow of side aeration, oxidized nitrogen almost entirely disappeared from the effluent, and the effluent then became putrescible. This experiment, however, does not conclusively show that aeration does not also take place through the sides of a filter with perforated walls, as the deterioration of the effluent might have been due to the unequal passage of the sewage liquor through the bed owing to impaired distribution, and so far as we are aware no experiments have been made which show conclusively how the interior of a percolating filter of medium-sized material is replenished with air.

On general grounds, we should think it better to arrange a given volume of medium-sized material in the form of a shallow rather than of a deep percolating filter. In this way better aeration would be maintained throughout the filter and the suspended solids in the liquor treated would be spread over a greater quantity of the filtering material.

Percolating Filters Constructed of Very Fine Material.

143. In filters constructed of very fine material, the material not only retains suspended matter on the surface, but also prevents the free access of air to the interior. When sewage liquor is applied to such a filter, almost the whole of the suspended matter is retained on the surface of the material, with the result that after a time the surface becomes completely choked. The filter has then either to be washed by upward flow, with simultaneous raking of the top few inches of the fine material, or it must be rested until the suspended matter on the surface is sufficiently dry to be raked off.

In the majority of cases, these filters are fed from a flushing tank, or the fine material itself is wholly relied upon for aiding uniform distribution. As showing that in the latter case (and presumably in the former also) a filter depends chiefly upon periods of rest for the access of air to the interior, we may quote the following experiment :—

At Prestolee, in Lancashire, there are three small filters which have a surface layer of very fine clinker : the material at the bottom of the filter is about one inch in diameter. The filters are entirely closed in at the sides, and at the bottom connect with the air through a single outlet valve only. The method of working the filters is simply to allow the septic tank liquor to flow on to the surface of one of them by means of half pipes, and then to percolate through to the outlet drains. The suspended matter in the tank liquor, being caught on the surface, soon chokes the fine material near the half pipes, and the liquor then gradually spreads over the whole surface of the filter. When the surface is about two-thirds or four-fifths ponded, the tank liquor is diverted to the second filter and the first is allowed to rest and dry off, after which the suspended matter is carefully removed with a spade.

144. In order to gain some idea as to how long it would be possible to work one of these filters without resting, the following experiments were made :—

On Wednesday, January 4th, 1905, at 2.30 p.m., septic tank liquor was turned on to Bed No. 1, which had previously been rested for $29\frac{1}{2}$ hours, *i.e.*, a shorter period of

rest than the usual two days. The first samples of effluent from the bed were drawn thirty minutes after the start, at which time the effluent had begun to flow out at a fair rate, and others were taken out from time to time, as shown in the table below. The experiment lasted until January 9th, at 4.20 p.m., *i.e.*, for fully five days, the weather for the greater part of this time being showery, but the flow of sewage never much above the normal.

During the course of the experiment, four samples of septic tank liquor were drawn, viz :—

On January 4th at 2.30 p.m.
On January 5th at 10.45 a.m.
On January 6th at 9.45 a.m.
On January 9th at 4.0 p.m.

These samples were very much alike in composition, and the figures of analysis are therefore averaged in the table, and placed in one column. Incidentally they show that the liquor is very weak, but this is quite normal for Prestolee.

	Average of 4 Septic Tank Liquors.	Effluents.					
Drawn		Jan. 4th., 30 minutes after starting filter.	Jan. 4th., 6½ hours after starting filter, the surface of which was then three quarters ponded.	Jan. 5th., 20¾ hours after starting filter, the surface of which was then four-fifths ponded.	Jan. 5th., 27½ hours after starting. Surface almost completely ponded	Jan. 6th., 43¾ hours after starting. Surface nine-tenths ponded.	Jan. 9th., 121½ hrs. after starting. Filter surface then completely ponded.
Analysed :		Jan. 5th.	Jan. 6th.	Jan. 6th.	Jan. 9th.	Jan. 9th.	Jan. 10th.

Oxygen in solution (when analysed) *c.c. per litre* †	—	5·6	4·2	5·1	0·0	1·0	0·7

* The figures in brackets indicate the number of estimations in each case.

† In comparing the figures for dissolved oxygen found on the day of analysis, it is important to note that these estimations were made at different intervals of time after the samples were drawn. Those which could not be examined at once were kept in ice, but the second sample of January 5th was at atmospheric temperature for two days after being drawn; this no doubt accounts for its oxygen being exhausted.

At 6½ hours after the start, the bed had become ponded over three-fourths of its surface and the ponding gradually increased, but with fluctuations, until the bed was completely under water.

Concurrently with this, the figures for ammoniacal nitrogen and for nitric nitrogen (no nitrite being present in any sample on the day of analysis) show that the oxidation gradually decreased as the experiment proceeded. The figures both for "oxygen absorbed" from permanganate and for dissolved oxygen absorption are less regular, but this is no doubt partly due to the fact that all the effluents could not be examined at equal intervals of time after they were drawn. After five days the effluent even from this very weak tank liquor became putrescible.

145. It is clear, therefore, that percolating filters of very fine material can only be worked for a certain limited time without being rested, and, in order to obtain the maximum amount of work out of a given quantity of fine material, it would seem better to arrange it in the form of a shallow rather than in the form of a deep filter, provided the distribution is efficient.

Depth of Fine Percolating Filters.

Reid, 27075–27164.

146. The question of the most suitable depth for fine filters was specially brought to our notice by Dr. George Reid, the Medical Officer of Health for the County of Staffordshire.

In connection with his investigation of the fine grain filters at Hanley, Dr. Reid collected samples at the following depths from the surface of the filters, viz. :—1 foot, 2 feet, 3 feet, and (the bottom) 4 feet 6 inches.

The analyses of these samples, and also of the septic tank liquor, the detritus tank liquor, and the original sewage, are given in the following table :—

Parts per 100,000.

———	Sewage.	Detritus Tank.	Septic Tank.	Filter 1 foot	Filter 2 feet	Filter 3 feet	Filter 4·5 feet

Nitrous Nitrogen day after collection	0·029	0·022	Nil	0·003	0·007	0·008	0·002
Column necessary to obscure test lines (inches)	0·5	1·6	1·5	Over 24	Over 24	Over 24	Over 24

From these experiments Dr. Reid had drawn the inference that, in the case of the Hanley sewage "the lower two or three feet of filter medium is absolutely unnecessary, and so far as the cost of construction of the filters is concerned, the expenditure might be reduced by about one half."

* From weak permanganate.

He also suggested that a much better result would be obtained from a given quantity of *fine* filtering material if it were arranged in the form of a shallow filter, than if it were arranged in the form of a filter 6 feet deep; and, further, that to estimate the amount of filter required for a given flow of sewage, in cubic yards, without reference to the depth of the filter, was open to objection, inasmuch as the lower layers of a fine filter were less efficient than the top one or two feet. Reid, 27145.

The points raised by Dr. Reid are of considerable importance, and we considered it desirable to make further experimental investigations in regard to them, especially as the results obtained at Hanley in respect of fine filters differed so materially from the results which we had obtained elsewhere with coarse filters.

Dorking experiments as to depth of filters.

147. Our experiments were carried out at Dorking, under the charge of Mr. E. H. Richards, our resident chemist. For the purpose of the experiments, we constructed two filters 4 feet 10 inches deep, one filled with fine material and the other with coarse material, and two filters 2 feet 5 inches deep, one filled with fine material and the other with coarse material.

For convenience the two deep filters were constructed in the form of one circular filter with a dividing partition between the coarse and fine material. The shallow filters were also constructed in a similar manner. The distribution was by means of revolving sprinklers, fed intermittently from small tipping troughs. At the suggestion of Dr. Reid, who very kindly gave every possible help in the planning of the experiment, the distribution was carefully tested before the experiment started and was found to be as perfect as could reasonably be expected. The flush of tank liquor (5 gallons) on to the filters took place as follows :—

During Experiment I. - - once every 7 minutes.

During Experiment II. - - once every $3\frac{1}{2}$ minutes.

The following table gives particulars of the four filters :—

Dorking Experimental Filters.

——	Material.	Depth of Material.	Size of Material.	Contents of filter.
				Cube yards.
Coarse Shallow Filter - -	Clinker.	2′ 5″	1″ to 4″ throughout.	5·14
Coarse Deep Filter - - -	Clinker.	4′ 10″	1″ to 4″ throughout.	10·28
Fine Shallow Filter - -	Clinker.	2′ 5″	Top 1′ $2\frac{1}{2}$″ of $\frac{1}{8}$″ to $\frac{1}{4}$″ diam. Bottom 1′ $2\frac{1}{2}$″ of $\frac{1}{4}$″ to $\frac{1}{2}$″ diam.	5·14
Fine Deep Filter - - -	Clinker.	4′ 10″	Top 2′ 5″ of $\frac{1}{8}$″ to $\frac{1}{4}$″ diam. Bottom 2′ 5″ of $\frac{1}{4}$″ to $\frac{1}{2}$″ diam.	10·28

The sewage treated in the experiments was drawn, by means of a bypass, from the Dorking outfall at a constant flow. It may be described as almost entirely domestic sewage of about average strength.

Table I. shows the figures of analysis given by 21 sets of average samples of the sewage taken from November, 1905, to November, 1906.

TABLE I.

Figures for Screened Sewage.

24-hours samples.

Parts per 100,000.	Average.	No. of estimations.
Ammoniacal Nitrogen (2·63 to 5·69)	4·65	21
Albuminoid Nitrogen (0·56 to 1·66)	1·00	20
Total Organic Nitrogen (1 17 to 3 11)	1·92	20

Total Nitrogen (4·51 to 5·88)	6·72	20
Oxygen absorbed at once at 27°C. (1·20 to 3·41)	2·38	21
Oxygen absorbed in 4 hours (6 37 to 14·77)	10·01	21
Solids in suspension (11·7 to 32·8)	21·50	21
Calculated strength* 96	—	—

* Strength expressed in terms of the number of parts by weight of oxygen required to oxidize 100,000 parts of sewage, arrived at on the basis of the formulæ suggested by Dr. McGowan—*see* p. 16 of this Report, and Dr. McGowan's Memorandum in Appendix IV.

The sewage, before filtration, was precipitated with ten grains of alumino-ferric and five grains of lime per gallon, and was then allowed to pass through a tank of sufficient capacity to give ten hours continuous flow settlement. The tank was cleaned once a week, as a rule, but twice a week in hot weather.

Experiment I. (*June* 17*th*, 1907, *to October* 17*th*, 1907.)

148. On June 17th, 1907, the four filters were started working at the rate of seventy-five gallons per *square yard* per day for each filter. This was equivalent to a rate of ninety-three gallons per cube yard for each shallow filter and 46·5 gallons for each deep filter. This small dose was intentional, the idea being to work the filters with gradually increasing volumes of liquor and to note the order in which the effluents deteriorated in quality. The above rate of working continued without cessation until October 17th, 1907. The surface material of the coarse filters was soon covered with a green growth as is usual at Dorking at that time of the year. The growth was thin and had no apparent effect upon the aeration of the filters or upon the passage of the tank liquor through the material.

The material in the two fine filters was comparatively free from growth, and at no time during this experiment did any ponding of the surface occur. The upper layers of the fine material swarmed with small red worms.

During the four months all the effluents and the precipitation liquor were examined by sets of average samples drawn hourly for eight hours every eight days.

The figures given in Table II. are therefore representative of the working of the filters under all conditions.

TABLE II.

Deep and Shallow Filter experiment.

Average Figures of Analysis for Precipitation Liquor and Effluents.

All Filters working at the rate of 75 gallons per square yard.

Twelve Analyses.

June 27th to September 27th, 1907.	Ammoniacal Nitrogen.	Albuminoid Nitrogen.	Nitrous Nitrogen.	Nitric Nitrogen.	Oxygen absorbed in 3 minutes at 27° C.	Oxygen absorbed in 4 hours at 27° C.	Dissolved oxygen taken up in 48 hours at 18° C.	Dissolved oxygen taken up in 5 days at 18° C.	Incubator test (Smell).	Solids in Suspension.	Centrifuge (Volumes).	Chlorine.	Rate of Filtration in Galls. per cube yard.
Precipitation liquor - - -	4·94	0·51	0·02	0·08	1·72	5·44	—	—	—	5·73, 3·53 (vol.) 2·20 (non-vol.)	60	—	—
Coarse shallow filter effluent - -	0·66	0·11	0·14	3·14	0·47	1·35 1·12 (paper filtered)	0·57	1·47 0·48 (paper filtered)	12+	1·53, 0·99 (vol.) 0·54 (non-vol.)	27	—	93
Coarse deep filter effluent - -	0·14	0·08	0·05	4·03	0·31	0·91 0·76 (paper filtered)	0·24	0·67 0·32 (paper filtered)	12+	1·28, 0·77 (vol.) 0·51 (non-vol.)	26	—	46·5
Fine shallow filter effluent - -	0·08	0·04	0·04	4·00	0·27	0·57	0·04	0·12	12+	—	None	—	93
Fine deep filter effluent - - -	0·03	0·04	Trace.	4·26	0·16	0·51	0·03	0·15	12+	—	Trace	—	46·5

The sign + means that the sample did not putrefy on incubation.

The precipitation liquor treated was fairly strong. It had a calculated strength * of about sixty-one.

The effluents from the two coarse filters were both very good, but the *liquid* portion of effluent from the deep filter contained only about two-thirds as much oxidizable matter as that from the shallow filter, as judged by the oxygen absorbed test. The difference is shewn by the following figures :—

	Effluent from the coarse shallow filter.	Effluent from the coarse deep filter.
Ammoniacal nitrogen	0·66	0·14
Nitric nitrogen	3·14	4·03
Oxygen absorbed in 4 hours by paper-filtered effluent	1·12	0·76
Dissolved oxygen taken up in 5 days by paper-filtered effluent	0·48	0·32

The effluents from the two fine filters were, for practical purposes, alike, the oxidation having been carried very far in each case, as is shown by the following figures :—

	Effluent from fine shallow filter.	Effluent from fine deep filter.
Ammoniacal nitrogen	0·08	0·03
Nitric nitrogen	4·00	4·26
Oxygen absorbed from permanganate in 4 hours	0·57	0·51
Dissolved oxygen taken up in five days	0·12	0·15

All four effluents may be classed as good to very good, and all the filters were sufficiently, or more than sufficiently, deep, for the volume and the strength of the liquid treated.

The results from the deep and shallow fine filters are in agreement with those obtained by Dr. Reid at Hanley. They show that, *with the amount of sewage liquor being treated*, the extra depth in the deep filter was not required ; or, in other words, that passage through the first half of the deep filter was sufficient to oxidize almost the whole of the oxidizable matter in the liquor put on the filter.

Salt Experiment I.

149. At the conclusion of this first experiment an attempt was made, as at Ilford, to find the approximate average time taken by the precipitation liquor to pass through each filter.

About 28 lbs. of common salt were dissolved in water, and half the solution was poured into the tipping-trough supplying each pair of filters, in such a way as to interfere as little as possible with the natural working of the distributors.

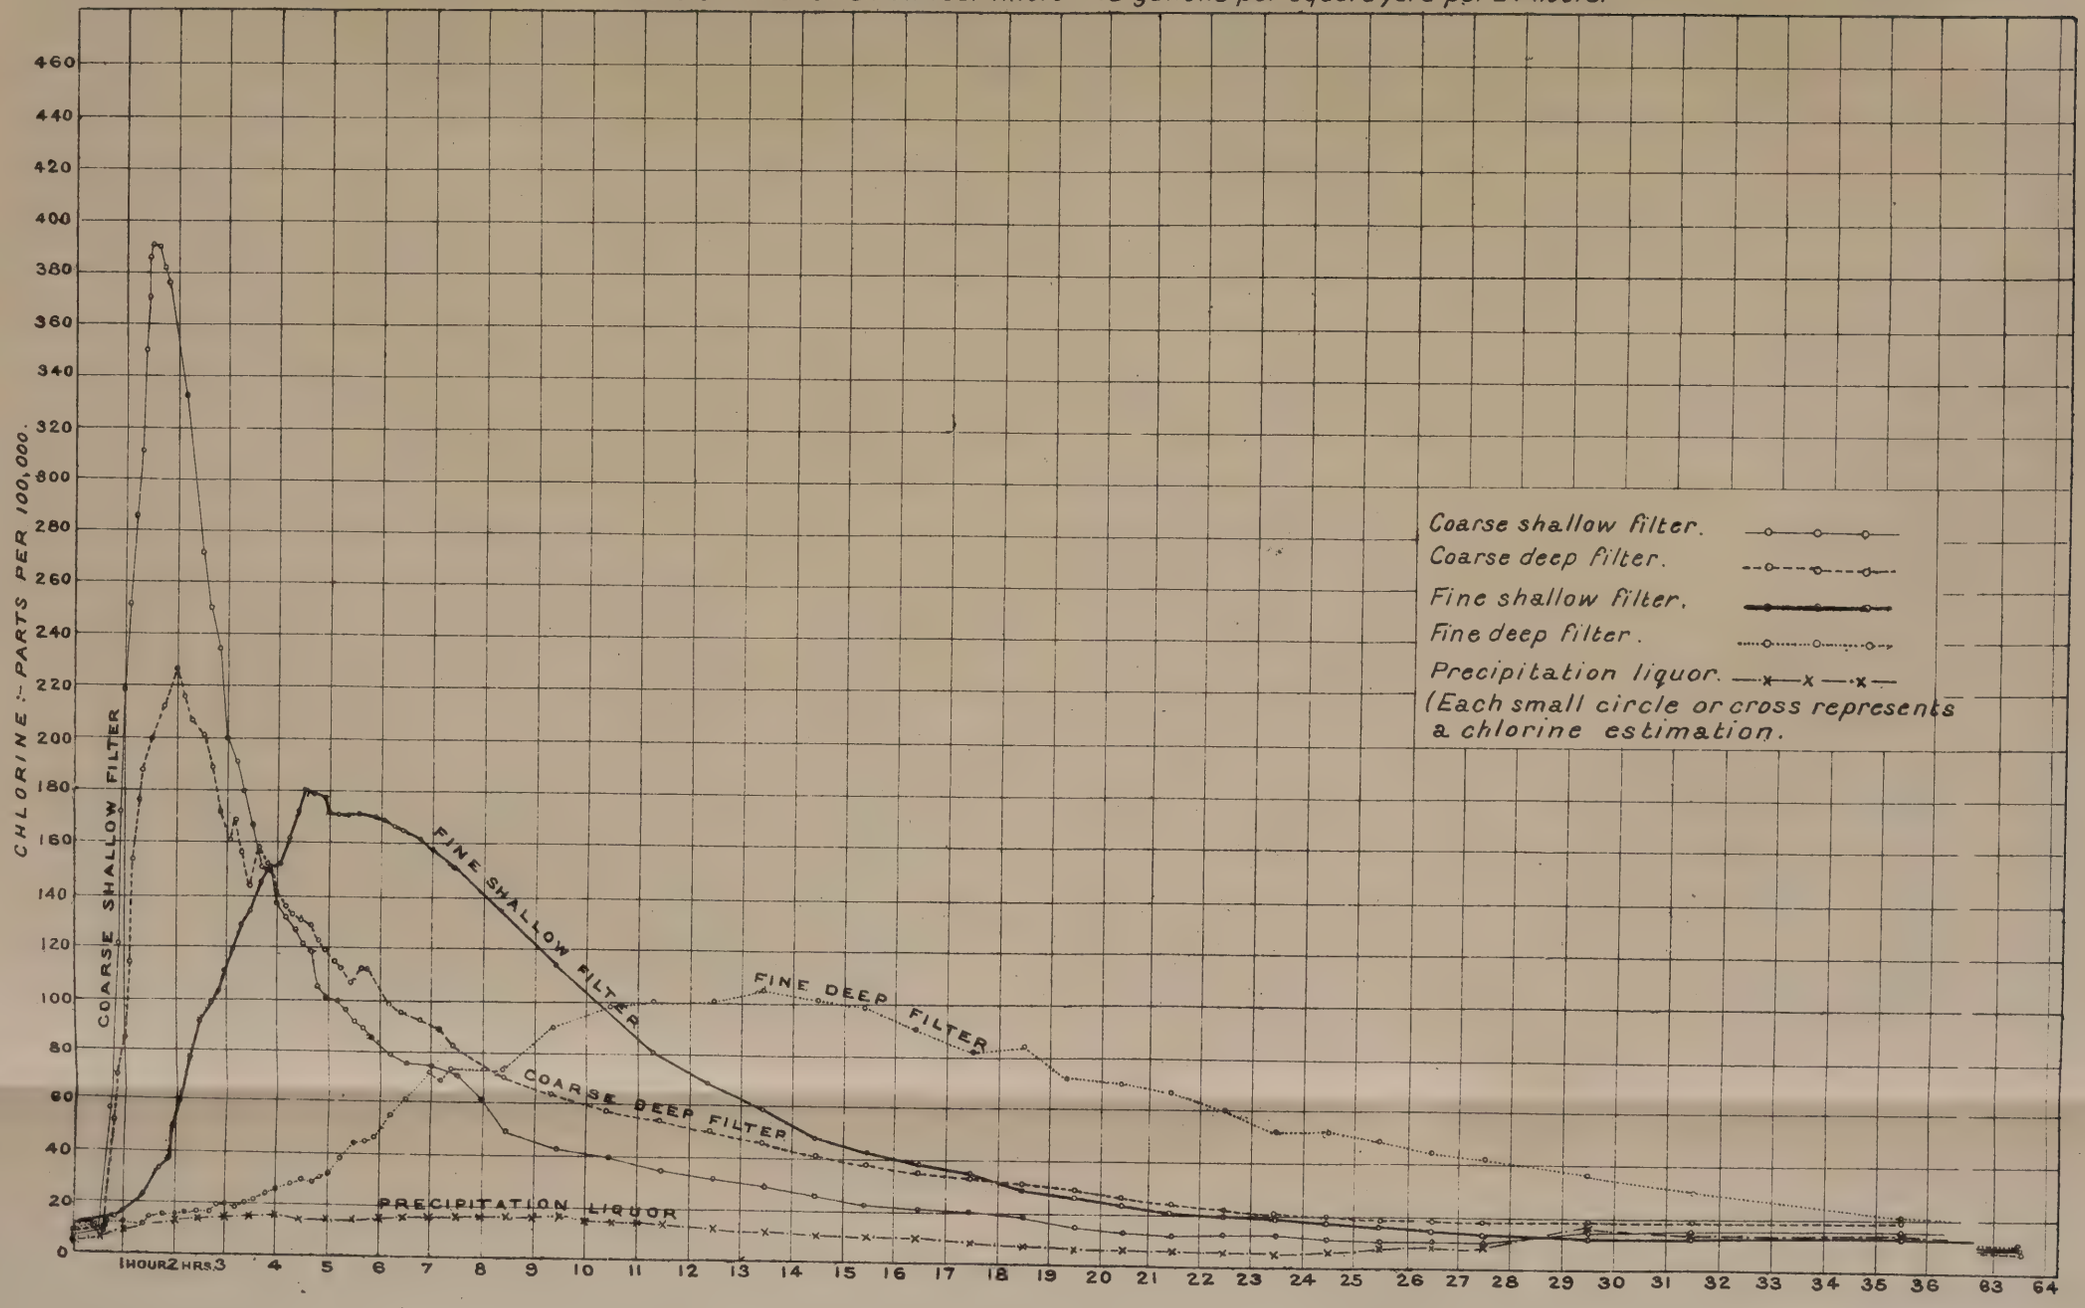
Approximately 7 lbs of salt were thus flushed on to each filter.

Samples of the four effluents were taken first at one minute intervals, and subsequently at longer intervals over a period of 56 hours, until the salt had apparently all passed through the filters.

The chlorine in these samples plotted against time of drawing is shewn in Diagram 2.

These curves suggest the conclusion that a sample of effluent drawn at a given time is composed of a mixture of liquid which has been in contact with the filtering material for times varying (in all four cases) from about thirty minutes or less, to something like sixty *hours* or more.

The proportion of liquid which has been in contact with the filtering material for a short time to the proportion of liquid which has been in contact for a long time would largely depend upon the depth of the filter, and upon the nature and size of the material of which the filter is composed.



* *See* section of this Report on Strength of Sewage, p. 15.

CURVES SHEWING THE RATES OF FILTRATION THROUGH THE TWO COARSE AND THE TWO FINE FILTERS AT DORKING, AS TESTED QUANTITIVELY WITH A SOLUTION OF SALT.

OCTOBER 9TH 1907.

Rate of filtration on all four filters = 75 gallons per square yard per 24 hours.

DIAGRAM 2.

Weller & Graham, Lith. London.

To draw any exact conclusions as to the average time of contact in each of the four filters appears to be almost impossible. We may, however, give the following ratios, etc :—

—	Total quantity of salt washed out of filter in 30 hours.		Time taken for half the average quantity of salt to wash out.		Hour line upon which the centre of gravity of the curve figure falls.		Total area enclosed by the curve figure.	
	Weight in lbs.	Proportion to 7 lbs	Hours.	Time ratio.	Hours	Hour line ratio.	Cubic inches.	Area ratio.
Coarse shallow filter - -	4·36	0·62	3·0	1·0	5·33	1·00	12·9	1.00
Coarse deep filter - -	4·59	0·65	5·5	1·8	9·0	1·63	13·0	1·01
Fine shallow filter - -	4·98	0·71	7·0	2·3	9·0	1·63	14·0	1·08
Fine deep filter - -	5·42 (39 hrs.)	0·77	14·5	4.8	17·0	3·10	14·0	1·08
Average - - - -	4·83	—	—	—	—	Average.	13·5	—

As judged by the time taken for half the average weight $\left(\frac{4{\cdot}83}{2}\text{lbs.}\right)$ of salt to issue in the effluent, the time of contact in the coarse deep filter was nearly double that given in the coarse shallow filter, and rather less than the time of contact given in the fine shallow filter. In the fine deep filter it was almost exactly double the time given in the fine shallow filter.

Upon this basis of calculation, the fine deep filter ought to give the best effluent, the fine shallow filter the next, the coarse deep filter the next, and the coarse shallow the worst. The quantities of oxidizable matter treated were not sufficient to give any true idea of the relative oxidizing power of each filter, but it will be seen that the figures of analysis do arrange the effluents in this order.

Experiment II. (*October 18th*, 1907, *to January 12th*, 1908.)

150. On October 18th, 1907, the rate of working was increased to 150 gallons per *square yard* per day for each filter. This was equivalent to a rate of 186 gallons per cube yard for each of the two shallow filters and 93 gallons for each of the two deep filters. This rate of working continued until December 22nd, when all the filters were given a week's rest in cold dry weather. On December 29th they were started again at the same rate, and from this time they worked without cessation until January 28th, when the experiment stopped.

The increased rate of working and the low atmospheric temperature showed their effects on the nitrification, the ammonia rising and the nitrate falling in all the effluents. Moreover, a grey growth (*Cladothrix dichotoma*, Cohn) made its appearance and began to flourish on the surface of the two coarse filters towards the end of October, gradually increasing in thickness during the two following months.

The same growth appeared on the surface of the two fine filters ; this also increased, but never to anything like the same extent as on the coarse filters. On November 20th local ponding began on both fine filters, being rather worse on the shallow filter than on the deep. On December 2nd both the fine filters were raked over for the first time, and as this was done afterwards whenever necessary, neither the growth nor the suspended matter caught in the top few inches of the fine clinker had very much effect upon the working of these filters. There is no doubt that the effect of the growth was much more marked in the case of the two coarse filters.

The severe frosts in January killed off the growths on the fine filters, and to a certain extent on the coarse filters also, but with the return of the milder weather the growth re-asserted itself. Although the filters were at times completely frozen over between the jets of the sprinklers, none of the effluents deteriorated seriously. The coarse deep filter suffered most in this way from its exposed position.

The averages of the figures of analysis are given in Table III.

They were obtained from samples drawn in an exactly similar way to those in Experiment I.

TABLE III.

Deep and Shallow Filter Experiment.

Average Figures of Analysis for Precipitation Liquor and Effluents.

All Filters working at the rate of 150 gallons per square yard.

Ten Analyses.

October 22nd, 1907, to January 12th, 1908.	Ammoniacal Nitrogen.	Albuminoid Nitrogen.	Nitrous Nitrogen.	Nitric Nitrogen.	Oxygen absorbed in 3 minutes at 27° C.	Oxygen absorbed in 4 hours at 27° C.	Dissolved Oxygen taken up in 48 hours at 18° C.	Dissolved Oxygen taken up in 5 days at 18° C.	Incubator test (smell)	Solids in Suspension.	Centrifuge (volumes).	Chlorine.	Rate of filtration in gallons per cube yard per day.
Precipitation Liquor - - -	4·13	0·50	0·09	0·19	1·44	4·85	—	—	—	5·70, 3·03 (vol.) 2·67 (non-vol.)	64	7·48	—
Coarse shallow filter effluent - -	0·99	0·16	0·08	2·23	0·41	1·26 0·87 (paper filtered)	1·00	2·42 0·52 (paper filtered)	10+	2·65, 1·75 (vol.) 0·85 (non-vol.)	53	7·05	186
Coarse deep filter effluent - -	0·55	0·10	0·07	2·69	0·27	0·94 0·79 (paper filtered)	0·51	1·40 0·42 (paper filtered)	10+	1·51, 1·09 (vol.) 0·42 (non-vol.)	34	7·07	93
Fine shallow filter effluent - -	0·86	0·11	0 05	2·80	0·34	0·90	0·46	1·03	10+	1·00 (approx.)	26	7·02	186
Fine deep filter effluent - - -	0·35	0·06	0 03	3·25	0·24	0·60	0·21	0·42	10+	0·25 (approx.)	5	7·02	93

In this second experiment, the precipitation liquor treated was distinctly weaker than it was in the first experiment. Its calculated strength was only fifty-four as against sixty-one. This was no doubt owing to the heavy rainfall in the last months of the year.

Comparing the effluents from the the two coarse filters, we have the following figures :—

	Effluent from the coarse shallow filter.	Effluent from the coarse deep filter.
Ammoniacal Nitrogen	0·99	0·55
Nitric Nitrogen	2·23	2·69
Oxygen absorbed in 4 hours by paper-filtered effluent	0·87	0·79
Dissolved Oxygen taken up by paper-filtered effluent in 5 days	0·52	0·42

It would have been expected that with the greater flow per cube yard the difference between the effluents from the two coarse filters would have become accentuated, but in actual fact it is, if anything, rather less than it was in Experiment I, though at the same time neither effluent was of quite such good quality. The explanation of this result is, we think, to be found in the development of growths upon the surface of the coarse material and some way down into it which took place during the experiment. This undoubtedly interfered with the normal working and, as will be shown later, altered the times of contact given. With regard to the effluents from the fine filters (which, it will be remembered, were in the first experiment practically identical), these showed a greater difference than before as is evident from the following figures :—

	Effluent from fine shallow filter.	Effluent from fine deep filter.
Ammoniacal Nitrogen	0·86	0·35
Nitric Nitrogen	2·80	3·25
Oxygen absorbed in 4 hours by paper-filtered effluent	0·90	0·60
Dissolved Oxygen taken up in 5 days	1·08	0·42

Some growth occurred on the fine filters, but it had much less effect upon the working of them than the growth had upon the working of the coarse filters, mainly because of the surface raking adopted.

So far as the coarse filters in Experiment II are concerned, the value of the comparison of the results was vitiated by the growth.

As regards the fine filter effluents, while both are good, that from the deep filter contained only about half the residual oxidizable matter as that from the shallow filter.

At the same time, the total amount of matter which was oxidized by the fine filter, 4 feet 10 inches deep, was little more than the total amount which was oxidized by the fine filter of half the depth.

As in Experiment I., all the filters continued sufficiently (or more than sufficiently) deep for the volume and strength of the liquor treated.

Salt Experiment 2.

151. At the conclusion of Experiment II another salt test was made in order to compare the curves obtained at this rate of flow (150 gallons per square yard) with those in Experiment I when the rate was 75 gallons per square yard.

The result is shewn in Diagram 3. Exactly the same amount of salt was used as before, viz. 7lbs. for each of the four filters, but as the flow of liquid was now doubled, the chlorine figures are correspondingly lower in each case.

Interpreting the curves in the same way as those of Diagram 2, we obtain the following figures :—

	Total quantity of salt washed out of filter in 23 hours.		Time taken for half the average quantity of salt to wash out.		Hour line upon which the centre of gravity of the curve figure falls.		Total area enclosed by the curve figure.	
	Weight in lbs.	Proportion to 7 lbs.	Hours.	Time ratio.	Hours.	Hour line ratio.	Cubic inches.	Area ratio.
Coarse shallow filter - - -	4·2	0·60	2·27	1·00	3·8	1·00	6·98	1·00
Coarse deep filter - -	4·87	0·69	3·00	1·32	5·6	1·48	7·96	1·14
Fine shallow filter - -	4·17	0·60	3·70	1·63	5·8	1·53	6·28	0·90
Fine deep filter - - -	4·36	0·62	6·30	2·77	9·4	2·48	6·98	1·00
Average - - - - -	4·40	—	—	—	—	Average.	7·05	—

It will now be seen that in the two coarse filters, especially in the shallow one, the time taken for half the average quantity of salt to wash out was distinctly more than half what it was in Experiment I.

The effect of this is to bring the ratio figures for average time of contact in the two coarse filters much nearer together, viz., 1·0 : 1·32 as against 1·0 : 1·8 in Experiment I.

The same thing is seen but to a lesser extent with the fine filters, where the ratio figures are 1·63 : 2·77 as against 2·3 : 4·8.

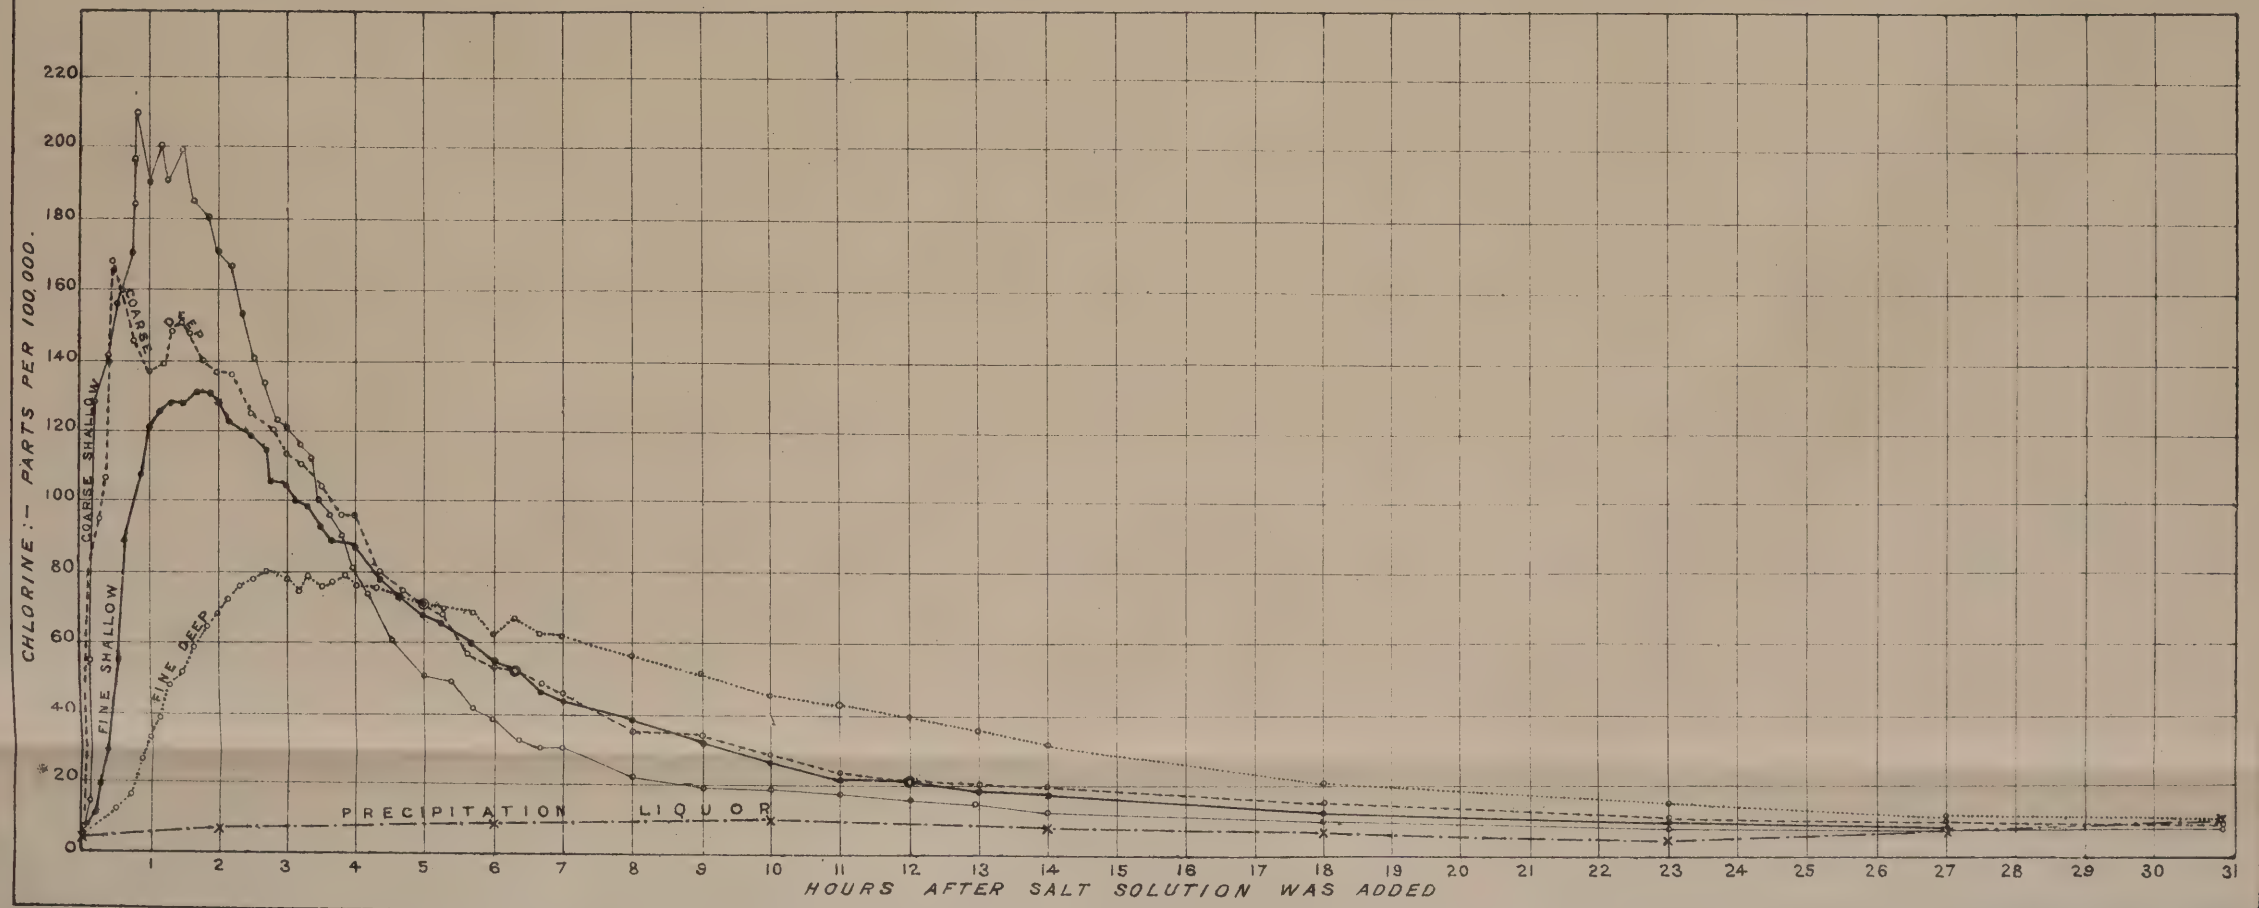
The figures of analysis run parallel with this, there being less difference between the two coarse filter effluents than in Experiment I. Further, the rate of filtration is now sufficient to bring about a difference in the figures of analysis for the fine filter effluents.

Salt Experiment 3.

152. The appearance of the filters at this time led us to surmise that the difference between the ratio figures of Salt Experiment 1 and those of Salt Experiment 2 was to be ascribed to the development of *Cladothrix dichotoma* on the filtering material, especially on the coarse material.

In order to satisfy ourselves as to this, we cut down the flow on to the filters to the original rate of 75 gallons per square yard *immediately* after the conclusion of Salt Experiment 2, and proceeded to make a third Salt Experiment. Apart, therefore, from the difference in the state of the filters, the conditions of this Experiment were precisely the same as in Salt Experiment I.

DIAGRAM 3.



CURVES SHOWING THE RATES OF FILTRATION THROUGH THE TWO DEEP AND THE TWO SHALLOW FILTERS AT DORKING, AS TESTED QUANTITIVELY WITH A SOLUTION OF SALT.

Rate of filtration on all four filters = 150 gallons per square yard per 24 hours.

Fine deep filter - - -	6·29	0·90	16·9	2·68	19·6	2·22	16·28	0·73
Average - -	6·54	—	—	—	—	—	18·13	—

The ratio figures for the time taken for half the average quantity of salt to wash out in this experiment were thus practically the same as in Salt Experiment 2, viz., 1·0: 1·32 and 1·0 : 1·44 for the two coarse filters and 1·63 : 2·77 and 1·62 : 2·68 for the two fine filters.

In other words, given a filter in the same state, the time of contact is inversely proportional to the rate of flow.

While, therefore, the growth interfered with the progress of the experiment as originally outlined, it has helped in a striking way to shew how close is the relationship between the time of contact and the quality of the effluent.

General Conclusions as to Depth of Percolating Filters.

153. Our Dorking experiments are not completed, and some points are not yet settled, but we think that the results obtained by other workers, together with those arrived at by us, bring out the following points fairly clearly :—

(1) That the deeper the filter the better the effluent. This holds both for fine and coarse material, assuming good distribution and aeration.

(2) For practical purposes and assuming good distribution, the same purification will be obtained from a given quantity of *coarse* material, whether it is arranged in the form of a deep or of a shallow percolating filter, if the volume of sewage liquor treated per cube yard be the same in each case.

Thus, a filter, 3 feet deep, worked at the rate of x gallons per square yard per day, would give similar results to a filter 6 feet deep, worked at the rate of 2 x gallons per square yard.

In the absence of clogging, the balance would be slightly in favour of the deep filter, because the greater the depth the more the errors of distribution would be neutralised. There must always be a limit of shallowness (say 3 feet), beyond which it would be unwise to go, for however good the distribution might be, if a coarse filter were constructed very shallow, a considerable proportion of the sewage would pass through by "short cuts."

(3) With regard to filters of *fine* material, if the liquid to be purified were absolutely free from suspended and colloidal solids, and if thorough aeration could be maintained, the statement just made for filters of coarse material might possibly hold good for filters of fine material also. In practice, however, these conditions can scarcely be maintained with large rates of flow, and we think that the greatest efficiency can be got out of a given quantity of *fine* material by arranging it in the form of a shallow filter rather than of a deep filter. But we are not in a position to make an exact quantitative statement as to the difference in efficiency of the two forms.

It is probable that for the treatment of a strong sewage liquor, the filter should not be quite so shallow as for a weak liquor, but the point has not been fully worked out.

(4) The extent of the purification effected by a percolating filter varies with the average length of time taken by the sewage liquor to pass through the filtering material, assuming that proper aeration of the filter is maintained.

Fowler, 22819.

Size of Material.

154. The size of the filtering material should depend, very largely, upon the amount and character of the suspended matter in the liquid to be filtered. Fine or medium-sized material undoubtedly produces the best effluents, so long as it is kept free from water-logging ; but, unless the rate of filtration is slow, such filters soon clog if much suspended matter is contained in the liquid which is being filtered.

At Leeds, screened crude sewage, containing about 50 parts of suspended matter per 100,000, was treated upon filters of coarse material (over 4 inches in diameter) for at least eight or nine months ; but it was found that when the same sewage was treated on a Ducat filter constructed of fine to medium clinker ($\frac{3}{8}$-inch to $\frac{5}{8}$-inch diameter), even at a slower rate, the filter became clogged in a month. The rates of filtration were as follows :—

Through the coarse filter ($11\frac{1}{2}$ feet deep)	-	52 gallons per cube yard per day.
Through the fine filter (10 feet deep)	-	45 gallons per cube yard per day.

In considering the question of size of filtering material, the character of the suspended matters in the sewage to be treated must also be taken into account.

No doubt the amount of fibre in the sewage was the chief cause of the very rapid choking of the fine Ducat filter at the Leeds works. As we have already mentioned, this filter became clogged within a month when screened sewage was put upon it, and with septic tank liquor, containing about 18 parts of suspended matter per 100,000, it completely choked after about two and a half years. The rate of filtration during the experiment with septic tank liquor was about 57 gallons per cube yard per day.

155. The following tables give particulars as to the size of filtering material in use at a number of places which we have had under observation.

Place.	Nature of Material.	Size of Material.	Depth of Material.	Amount of suspended matter in liquor treated. Parts per 100,000.		Calculated strength of liquor treated.	Method of Distribution.	Whether delivery of liquid is Continuous or Intermittent.	Rate of filtration in gallons.		Condition of Filters.	Remarks.
				Hourly samples in dry weather.	Average of chance Samples.				Per square yard per 24 hours.	Per cube yard per 24 hours.		
Treatment of Crude Sewage.												
Hendon - -	Clinker.	½ in. to ¾ in.	8 ft.	20	—	107	Tipping troughs.	Continuous.	125	40	Good after eight years.	Experimental Ducat filter. Fixed quantity treated daily.
Leeds - -	Clinker.	⅜ in. to ⅝ in.	10 ft.	—	85	173	Tipping troughs.	Continuous.	83	25	Clogged after one month.	Experimental Ducat filter. Fixed quantity treated daily.
Leeds - -	Clinker.	Over 4 ins.	11·5 ft.	—	53	123	Sprinkler.	Intermittent.	200	52	Choked with growth after 21 months.	Experimental Leeds filter. Fixed quantity treated daily.
Treatment of Settled Sewage.												
Clifton - -	Sand and cinders.	Very fine to coarse.	4 ft.	24	—	123	By fine material on surface.	Intermittent.	20·8	15·6	Good after fourteen years. Filters scraped every three months.	Six times the dry weather flow dealt with in storm times.
Dorking - -	Clinker.	2 ins. to 4 ins.	5 ft. 7 in.	—	9·4	80	Sprinkler.	Continuous.	223	120	Good after two years.	Experimental process. Fixed quantity treated daily.
Leeds - -	Clinker.	Over 1½ ins.	9 ft. 6 in.	—	12	69	Sprinkler.	Continuous.	200	63	Unchanged after one year.	Experimental process. Fixed quantity treated daily.
Little Drayton -	Granite.	⅜ in. to ¾ in.	7 ft. 6 in.	20	—	165	Tipping troughs.	Continuous.	48	19·5	Upper part of material requires washing after three or four years.	
Treatment of Septic Tank Liquor.												
Accrington -	Coke or clinker.	2 ins. to 4 ins.	9 ft. 3 in. to 7 ft.	—	—	92	Sprinkler.	Continuous.	425	140	Good after four to eight years.	Twice the dry weather flow dealt with.
Birmingham -	Broken brick, granite or slag	Medium to coarse.	—	—	7·3	159	Nozzles.	Continuous.	165	82	Good after three or four years.	
Caterham -	Coke.	⅜ in. to 3 ins.	5 ft.	12·6	—	161	Perforated pipes.	Intermittent.	51	30·7	Good after ten years.	Fixed quantity treated daily.
Dorking - -	Clinker.	2 ins. to 4 ins.	5 ft. 7 in.	—	9·5	82	Sprinkler.	Continuous.	223	120	Good after two years.	Experimental process. Fixed quantity treated daily.
Guildford -	Coke.	Over 2 ins.	6 ft.	16	—	125	Sprinkler.	Intermittent.	102	51	Good after nine months.	Experimental process. Fixed quantity treated daily.

Place.	Nature of Material.	Size of Material.	Depth of Material.	Amount of suspended matter in liquor treated. Parts per 100,000.		Calculated strength of liquor treated.	Method of Distribution.	Whether delivery of liquid is Continuous or Intermittent.	Rate of filtration in gallons.		Condition of Filters.	Remarks.
				Hourly samples in dry weather.	Average of chance samples.				Per square yard per 24 hours.	Per cube yard per 24 hours.		
Hanley - -	Saggars.	$\frac{1}{4}$ in. to $\frac{1}{2}$ in.	5 ft.	—	7·6	54 ?	Sprinkler.	Intermittent.	206	124	Upper part of material requires washing after four or five years.	Six times the dry weather flow dealt with.
Huddersfield -	Clinker.	$1\frac{1}{2}$ ins. to 4 ins.	7 ft.	—	13	77	Sprinkler.	Continuous.	360	155	Good after one year.	Experimental process. Fixed quantity treated daily.
Leeds - -	Coke.	Over $1\frac{1}{2}$ ins.	9 ft. 6 in.	—	18	76	Sprinkler.	Continuous.	200	63	Good after four years.	Experimental process. Fixed quantity treated daily.
Prestolee -	Cinders and gravel.	Fine to coarse.	5 ft.	3·2	—	22	By fine material on surface.	Intermittent.	92	55	Good after eight years. Surface of material is scraped once a month.	Whole of storm water dealt with.
Rochdale - -	Coke.	$1\frac{1}{2}$ ins. to 4 ins.	9 ft.	5·3	—	83	Sprinkler.	Continuous.	424	141	Good after seven years.	Experimental process. Fixed quantity treated daily.
York - -	Clinker.	$1\frac{1}{2}$ ins. to $3\frac{1}{2}$ ins.	6 ft. 6 in.	5·3	—	58	Sprinkler.	Continuous.	360	150	Good after six years.	Fixed quantity treated daily.
Treatment of Precipitation Liquor.												
Chorley - -	Sand, polarite and gravel.	Very fine to coarse.	3 ft.	3	—	50	Flush tank.	Intermittent.	525	525	Good after twelve years. Beds washed by upward flow about once a week.	Rather more than dry weather flow dealt with.
Dorking - -	Clinker.	2 ins. to 4 ins.	5 ft. 7 in.	—	5·5	56	Sprinkler.	Continuous.	392	211	Good after two and a half years.	Experimental process. Fixed quantity treated daily.
Horfield - -	Clinker.	3 ins.	7 ft. 5 in.	2·5	—	36	Stoddart trays.	Continuous.	478	190	Good after five years.	Whole of storm water dealt with.
Leeds - -	Coke.	Over 3 ins.	6 ft.	—	6·3	52	Sprinkler.	Intermittent.	100	50	Unchanged after nine months.	During storms rate of filtration was largely increased.
Normanton -	Sand, polarite and gravel.	Very fine to coarse.	3 ft. 3 in.	14·0	—	112	By fine material on surface.	Intermittent.	106	98	Good after ten years. Filters are brushed over after each application of tank liquor and washed by upward flow every three months.	Fixed quantity treated daily.
Withnell - -	Sand, polarite and gravel.	Very fine to coarse.	3 ft.	2·0	—	81	Flush tank.	Intermittent.	68	68	Good after seven and eleven years. Beds raked over every week and washed by upward flow two or three times a year.	Some storm water dealt with.

NOTE.—The calculated "strengths" of the above sewage liquors are only to be taken as approximate and this more especially in the case of the sewages, etc., from Birmingham, Hanley, Huddersfield and Leeds; at those places the 4 hours "oxygen absorbed" figure is obtained with *weak* permanganate and we have only been able to make an *average* allowance for this.

Methods of Feeding Percolating Filters.

156. The main object to be aimed at in feeding a percolating filter is to deliver the liquid uniformly over the whole area in such a way that each particle of material receives an equal quantity of liquor.

A distributor should comply with the following requirements :—

It should distribute the liquid uniformly over the whole filtering area ;

Its working should not be affected by atmospheric conditions, such as wind, frost, etc. ;

It should be capable of adjusting itself to large variations in the flow, *i.e.*, it should deliver equally well the small flow of night sewage and the increased flow during storms.

The distribution should not be liable to be affected by the stoppage of small holes by the suspended matter of the sewage or tank liquor ;

It should be easy to clean ;

The points at which the moving parts of the distributor are in contact with the stationary parts, or with the parts which have a different motion, should, as far as possible, be separated from the liquid which is being distributed.

In selecting a distributor, it would be necessary to consider the head of water, or other power required to work it, and, of course, the question of cost.

157. At the places which we have had under observation we have had experience of six forms of distribution. We have made no comparative tests of the various forms, and we therefore only propose to offer certain general observations in regard to them.

The forms of which we have had experience may be classified as follows :—

(1) A sprinkler which moves, either automatically or by applied power, dropping or spraying the liquid as it rotates or travels backwards and forwards over an area of filtering material ;

(2) A stationary form of distributor, in which the liquid to be distributed is carried over the filter area by means of pipes, and forced under head of water through a large number of small orifices, so that it is broken up into fine jets ;

(3) A form of distribution in which definite volumes of liquid are automatically delivered in flushes ;

(4) Distribution by means of a very fine material laid on the surface of the filter, the liquid being by this means spread over the whole, or the greater part, of the filtering area ;

(5) Dripping trays, a stationary form of distributor, invented by Mr. F. Wallis Stoddart, by which the sewage liquid is carried over a filtering area in perforated trays of corrugated iron, from which it falls upon the filtering material in a succession of drips ;

(6) Tipping troughs. A stationary form of distributor, consisting of troughs balanced on pivots in such a way that, when filled with liquid, they tip and then return to their original position.

Type No. 1.—As regards moving sprinklers we may make the following observations :—

(*a*) Unless driven by applied power, which must obviously increase the cost of distribution considerably, they are seriously affected in their distribution by wind, and by severe frost and snow. In the case of light revolving sprinklers, they are not infrequently brought to a standstill by the wind. Where the filter is a small one, this disadvantage may to a considerable extent be overcome by building wind screens round the filter or by raising the retaining walls, but on a large works we should think that this would be impracticable, and with large filters not very effective.

(*b*) Automatic revolving sprinklers, when used intermittently (*i.e.*, when fed from a flushing tank), are capable of adjusting themselves to large variations of flow, but when used continuously, without a flushing tank, their rates of working can only be varied within somewhat narrow limits.

(*c*) The forms of sprinkler in which the tank liquor is delivered to the bed through a number of small holes need a considerable amount of attention. The arms require to be brushed out at least once a day, unless the tank liquor happens to be exceptionally free from suspended matter, or not likely to produce fungoid growths.

Type No. 2.—Distribution by means of perforated pipes or nozzles laid over a filtering area is almost always rather unequal, and this would be a disadvantage, except in the case of fairly deep beds constructed of fine or medium material, or deep beds (say, eight feet or more) of coarse material. This method of distribution, moreover, needs a considerable head of liquid for proper working, and also requires constant attention to keep the pipes and distributing holes clean and free.

At Birmingham, where the nozzle form of distributor is in use on a large scale, for each acre and a half of filter one man is constantly employed night and day in cleaning the nozzles. The constant walking over the surface of a filter is a distinct drawback, but assuming that the occupation is not dangerous to the workman, we think that this method of distribution will, in many cases, be found efficient and cheap.

Watson, 25008. Mr. Watson, of Birmingham, has made a careful comparison of various methods of distribution, and it will be seen from his evidence that, on account of cost, he prefers the system of spraying nozzles to other forms of distribution.

Type No. 3.—This method of distribution would only be suitable in a limited number of cases. Where the distribution is by means of flushes, the upper part of the bed should be made of very fine material, such as sand. With this type of filter the surface has to be constantly washed and cleaned, and it is therefore important that the tank liquor should be comparatively free from suspended matter. Owing to the difficulty of obtaining from a strong sewage a tank liquor containing only a small quantity of suspended and colloidal matter, this type of distribution is not well adapted for cases in which strong sewage has to be treated.

Type No. 4.—The distribution obtained by spreading the liquid to be treated over a filtering area covered with a layer of very fine material, such as soil, sand, or clinker dust, etc., does well either for strong or weak sewages; but unless the fine material on the surface of the bed is kept closely packed, there is danger, when the bed is first brought into use, of the liquid passing too rapidly to the drains. It would seem advisable, therefore, where this method of distribution is adopted, that the filter should be constructed throughout of fine to medium material, except round the drains.

Types Nos. 5 and 6.—Tipping troughs and dripping trays are, in our opinion, more suitable for small than for large installations. They can adapt themselves to large variations of flow, and in the case of small or medium-sized works, where constant supervision is not available, this is a great advantage. We may add that these trays are better suited for the distribution of a large volume of weak liquid than a small volume of strong liquid.

The distribution is seldom perfect by either of these forms of distributor, and consequently it is advisable to have deep beds where they are adopted. Further, owing to the fact that the delivery of liquid in both cases is more or less constant, medium-sized or coarse material should be used, to prevent ponding.

A certain amount of supervision is necessary as a tray may become blocked or a trough may fail to tip. The trays would require to be looked at about once a day, we think, and tipping troughs about twice a day ; but, beyond this, little attention is required. The distribution in both these forms is divided up into a number of units, and it is very unlikely that more than one or two units would get out of order at a time and that the distribution would be bad over a whole filtering area.

That tipping troughs are liable to be completely put out of action by severe frost we have seen exemplified at Little Drayton, and although we have had no experience of the same kind with regard to the trays, we should think that these were also liable to be affected by severe frost, though in their case distribution would never cease altogether.

Risk of Nuisance.

158. All forms of distribution on percolating filters are liable to give rise to nuisance from smell, if a strongly smelling liquor has to be dealt with. In the case of trays or tipping troughs the smell is confined more or less to the immediate vicinity of the filter, and it may be largely done away with at small works by providing an inexpensive form of cover for the filter. The nozzle form of distributor is naturally the most liable to give rise to smell, but moving sprinklers are almost equally bad in this respect.

Some Observations on the Most Convenient Superficial Area for a Percolating Filter.

159. So long as due regard is had for economy, the main consideration in laying out an area of percolating filters is to arrange the area so that portions of it may be put out of work without interfering with the general working of the plant.

If, for instance, at a small sewage works the whole of the sewage was treated upon one percolating filter fed by one sprinkler, any stoppage of that sprinkler would, unless land or some other means of disposal were available, result in the temporary discharge of a large quantity of unpurified sewage into the watercourse.

Experience has not shown that it is **necessary* for purposes of aeration to expose the sides of a percolating filter to the atmosphere, in order to obtain good results, and there would seem to be no reason, beyond engineering considerations, such as configuration of site, etc., for splitting up an area of percolating filter into units, provided that any part of that area could be cut out and rested, when necessary, without interfering with the general purification. The particular arrangement of the works would therefore depend very largely upon the form of distributor employed.

The size of a revolving distributor, for instance, has economic limits, and if this method of distribution were adopted the filter area would have to be split up into units corresponding with these limits.

The method of distribution by flushing fixed quantities of sewage liquid over percolating filters, constructed with a surface layer of very fine material, necessitates that the filter units should be small. Otherwise the flush of liquor cannot be made to spread evenly over the whole surface of the filter. This kind of filter has also to be washed or scraped at short intervals of time, and allowance must consequently be made for this.

Distribution by a power-driven distributor moving over a rectangular bed also has its limits, for, although the working of such a distributor can be regulated so as to rest the ends of a rectangular bed, it would appear to be difficult to feed the

* Some experiments which we carried out at Hendon, with the Ducat filter, indicated that open sides may be of advantage for the treatment of crude-screened domestic sewage, on a rather fine perolating filter Other work has prevented us from completing these experiments.

ends while resting the middle portion of the area. Further, if the bed were *very* long, large quantities of liquor would have to be fed on to each portion of filter at long intervals of time, instead of small quantities at short intervals.

With stationary distribution by means of nozzles, perforated pipes, dripping trays or tipping troughs, there would appear *in principle* to be no limit of size, for portions of a large area fed by such means could be cut out or brought in at will, without interfering with the general purification.

Where moving sprinklers are used, it would be cheaper to limit the number of units to a minimum, but the whole filtering area should comprise not less than three units so as to allow of cleaning and resting.

In the arrangement of a percolating filter area at a very large works, other considerations would have to be taken into account, such, for example, as the size of feed pipes, and the distance which the workmen would have to walk upon the material in order to get at different parts of the filter.

In regard to this question we may refer, particularly, to the evidence of Dr. Fowler, 23020, Mr. Watson, 25015, Dr. Reid, 24432 (131), and Messrs. Willcox and Raikes, 26114.

Construction of the Base of Percolating Filters.

160. In a percolating filter of *coarse* material, large quantities of suspended matter quickly work their way through the filter. If this suspended matter is not allowed to come away with the effluent, the bottom layers of the filter will become choked, and this will interfere with the working of the filter, not only for mechanical reasons, but also by preventing aeration. In such a filter, therefore, it is necessary to make provision for the free passage of suspended matter through the material and into the effluent drains, so that it can be completely carried away from the bed and dealt with subsequently.

In a percolating filter of *medium* or *fine* material, where the bulk of the suspended matter is caught and held in the upper part of the filter, the free base would not seem to be an absolute necessity. If, however, the suspended matter is not removed from the upper part of the filter by washing or riddling, it will eventually find its way to the bottom of the filter.

In any case the working of a percolating filter depends primarily upon the free passage of air through the bed, and, for this reason, we should say, in general, that it is advisable to construct the lower portions of all percolating filter, fine as well as coarse, as open as possible

If, in a filter constructed of medium or fine material, a bottom layer of large pieces is relied upon wholly for the aeration of the bed and for the free passage of liquid to the drains, it is obvious that great care must be taken in selecting this coarse material. Any serious disintegration at the bottom of the filter would result in parts of the filter becoming water-logged.

Choking of Percolating Filters.

161. Unless the material is coarse enough to allow the free passage of suspended matter, percolating filters are liable to become choked. Within ordinary practical limits, the rate of choking would depend upon the actual quantity of suspended matter delivered to the surface of the bed. At Leeds, for instance, it was found that carefully screened sewage, containing 80 parts of suspended matter per 100,000, when put upon a percolating filter composed of clinker $\frac{3}{8}$ inch to $\frac{5}{8}$ inch diameter, ten feet deep, had the effect of completely choking the surface within a month, notwithstanding the fact that the rate of filtration never exceeded 25 gallons per cube yard per day. When, however, septic tank liquor containing only about 18 parts of suspended matter per 100,000 was substituted for the screened sewage, the same filter gave good results without clogging for two years, though the rate of filtration was doubled. At the end of that time it was necessary to rest the bed and fork the surface, and after three years, owing to internal clogging, it became necessary to stop the experiment.

If a clogged filter of medium or fairly coarse material is rested, the suspended matter which causes the choking becomes granular, and can eventually be washed out of the filter. To some extent this applies also to a filter composed of very fine material, but in that case by far the greater proportion of the suspended matter remains on or near the surface and can only be got rid of by removing the clogged material and washing it, or exposing it for some time to the air, and eventually riddling it dry. When coarse material is used in a percolating filter there is apparently little danger of the filter becoming clogged, unless the sewage contains much fibre or is liable to give rise to fungoid growths, or unless serious disintegration of the material takes place. We have had no experience of such a filter becoming clogged with suspended matter when dealing with domestic sewage. At Accrington, coarse percolating filters have been in use for the treatment of septic tank liquor for eight years, and have not clogged. At Horfield, a coarse percolating filter treating precipitation liquor and fed by means of dripping trays ran uninterruptedly until it was dismantled after five years' work. At York, coarse filters have been in use for the treatment of septic tank liquor, without interruption, for four years. There are, in fact, a number of such instances. This kind of filter, however, seems to be liable to choke as the result of surface growths (*see* page 97). Where there is much fibre in the liquid to be treated (and the same thing would no doubt apply to grease and hops, etc.), percolating filters of even very coarse material may choke up. At Leeds, a percolating bed which was constructed of coarse coke, showed signs of becoming choked after having received septic tank liquor for eight and a half months. The primary cause of the choking was, we think, the fibrous character of the suspended matter, but there was a considerable development of growth on the surface of this bed at the same time.

The choking of a percolating filter constructed of medium-sized material (say $\frac{1}{4}$ inch to $\frac{5}{8}$-inch diameter) takes place at or near the surface, the material below this remaining fairly clean. We have seen examples of this at Salford, Hanley, Chesterfield, Birmingham, and Hendon, though at none of these places was the choking serious. At Market Drayton and Leeds, however, the upper portions of the filters had to be washed or renewed after about three years' work. The following table shows the amount of suspended matter, the rate of filtration, and the condition of the filters at the above places :—

Place.	Nature of material.	Size of material.	Amount of suspended matter in tank liquor treated. Parts per 100,000.	Rate of filtration in gallons.		Condition of filters.
				Per square yard per 24 hours.	Per cube yard per 24 hours.	
Leeds - - -	Clinker	$\frac{3}{8}$ in. to $\frac{5}{8}$ in.	80	83	25	Clogged after 1 month.
Market Drayton -	Granite	$\frac{3}{8}$ „ $\frac{3}{4}$ „	25	50	20	Upper part of material required washing after about 4 years' work.
Hendon - -	Clinker	$\frac{1}{2}$ „ $\frac{3}{4}$ „	20	125	40	Good after 8 years.
Leeds - - -	„	$\frac{3}{3}$ „ $\frac{5}{8}$ „	18	200	57	Bed seriously clogged after $2\frac{1}{2}$ years.
Chesterfield -	„	$\frac{1}{4}$ „ 2 „	12	90*	40*	Good after 6 years.
Birmingham -	Broken brick and granite	$\frac{1}{2}$ „ 3 „	8	155	77	Good after 3 or 4 years.
Hanley - -	Saggars	$\frac{1}{4}$ „ $\frac{1}{2}$ „	5	206	124	Upper part of material would probably require washing every 4 or 5 years.
Salford - -	Clinker	$\frac{3}{16}$ „ $\frac{3}{4}$ „	3	318	151	Good after 5 years. Top foot of material renewed on 10 per cent of area after 3 or 4 years, and rest of area dug over.

* Dry-weather rates of flow. In storm times these filters take four times the dry-weather flow.

We have had no experience of the washing of percolating-filter material on a practical scale ; but, from the evidence given as to the cost of washing contact-bed material, we should estimate that the cost would be approximately 1s. 6d. to 2s. 6d. per cube yard, if done by machinery on a large scale, and from 2s. 6d. upwards per cube yard, if done by hand on a small scale.

Growths on Percolating Filters

162. At a number of places thick, gelatinous, fungoid growths have at certain periods of the year (usually in the winter or early spring) developed upon the surfaces of percolating filters to such an extent as to cause serious ponding and consequent deterioration of the filter effluent. On the other hand, at other places, where apparently similar growths are present in small quantities on the surface of the material, they do not increase to any marked extent, and no ponding arises from this cause. Tables I. and II. give examples of each kind of place.

TABLE I.—Places where growths upon the surface of percolating filters have caused trouble.

Place.	Material used in filter.	Size of Material.	Mode of Distribution.	Whether delivery of liquor is continuous or intermittent.	Kind of liquor treated.	Amount of suspended matter in the liquor. Parts per 100,000.	Remarks as to growths.
Dorking	Clinker.	Coarse to medium.	Sprinkler.	Continuous.	Precipitation liquor.	8	The filters were started on Nov. 16th, 1905, and a pinkish-yellow filamentous growth made its appearance a fortnight later. This flourished until May of the following year, when it died away. During the last five weeks of this period the effluent from the filter was bad.
	Clinker.	Coarse to medium.	Sprinkler.	Continuous.	Septic tank liquor.	8·1	In both these cases, a grey-brown amorphous growth made its appearance at the same time as the growth on the filter treating precipitation liquor, but it did not flourish to such an extent, and never interfered seriously with the working of the filter. It practically disappeared during the early part of May.
	Clinker.	Coarse to medium.	Sprinkler.	Continuous.	Settled sewage.	10·5	
Guildford	Coke.	Coarse.	Sprinkler.	Intermittent.	Septic tank liquor.	15·9	This experimental filter was started in August, 1906. A grey-brown filamentous growth appeared on surface of the coke during the last months of that year, and increased seriously after frosty weather in January, 1907. The growth began to die away in the early summer.
Kingston	Clinker.	Coarse.	Sprinkler.	Continuous.	Precipitation liquor.	1·5	A short fibred grey growth appears annually on the surface of the filter, commencing about November and dying off in March. In the winter months it forms an almost impervious mat on the surface of the filter, the effluent becoming bad in consequence.
Leeds	Clinker.	Coarse.	Sprinkler.	Continuous.	Septic tank liquor.	18	The filter was started on March 9th, 1899, and ran till May 8th of the same year, when the effluent deteriorated in quality owing to the bed having become covered with an abundant gelatinous mycelium-like growth (pylobolus). On July 10th some very coarse coke was put on the surface of the bed, and from that time it was found possible to run for periods of about three months before the surface choked with the growth. When this occurred the coke was simply forked over.
	Clinker (6 inches of gas coke on surface).	Very coarse.	Sprinkler.	Continuous.	Crude sewage.	5·3	The filter was started on December 23rd, 1901. Almost from the first trouble arose from the thick pylobolus growth forming on the surface; this closed the interstices of the gas coke, and so gave rise to ponding and bad distribution. On March 1st, 1902, the coke was removed, and the bed from that time gave good results until the winter of 1902–3, when choking again occurred.

TABLE II.—Places where percolating filters have been run without any trouble from growths.

Place.	Material used in filter.	Size of material.	Mode of distribution.	Whether delivery of liquor is continuous or intermittent.	Kind of liquor treated.	Amount of suspended matter in the liquor. Parts per 100,000.	Remarks as to growths.
Accrington	Clinker	Coarse	Sprinkler	Continuous	Septic tank liquor	19	Only very slight signs of growth on the surface of the material after six years' work.
Birmingham	Clinker	Coarse to fine	Nozzles	Intermittent	Septic tank liquor	7·3	Only slight signs of growth after a year.
	Broken brick	Coarse to fine	Nozzles or sprinkler	Continuous or intermittent	Septic tank liquor	7·3	Only slight signs of growth after a year.
	Broken granite	Coarse to fine	Nozzles or sprinkler	Continuous or intermittent	Septic tank liquor	7·3	Only slight signs of growth after a year
Chorley	Sand	Very fine	Flushing tank	Intermittent	Precipitation liquor	2	No growth after eight years. Filters washed every week.
Hanley	Saggars	Fine	Sprinkler	Intermittent	Septic tank liquor	4·4	No growth after four years.
Horfield	Clinker	Coarse	Dripping trays	Continuous	Precipitation liquor	2·5	No growth after four years
Huddersfield	Clinker	Coarse to medium	Sprinkler	Continuous	Septic tank liquor Precipitation liquor Settled sewage	13·1 7·0	No serious signs of growth on any beds.
York	Clinker slag, coke, broken brick	Coarse to medium	Sprinkler	Continuous	Septic tank liquor	5·3	No growth after four years.

163. So far as we are aware, such growths have not been made the subject of systematic study in connection with sewage disposal, and little appears to be known as to the conditions under which they flourish. As will be seen from Table I., however, a pylobolus growth appeared upon the surface of a percolating filter treating septic tank liquor at the Leeds sewage works. In their Report on Experiments in Sewage Disposal, City of Leeds, 1905, p. 140, Colonel Harding and Mr. Harrison make the following remarks on the subject :—

"A few words must be added in regard to the difficulty of the fungoid "growths which arise in dealing with Leeds sewage on percolating filters, and "which, with any but very coarse material, soon choke the air spaces, and cause "the sewage to pond on the surface. The growths were less with partly settled "sewage than with the crude sewage and as in other cases they did not spread far "down into the filter, not more than from 6 to 12 inches at the most, it would "seem that light is required for their development."

"On the other hand, the holes in the sprinkler tubes were constantly choked "with these growths, so that they required to be daily cleansed; but it is more "likely that this was due to the fungus which forms in the open channels leading "to the sprinkler being washed forward into the tubes than to the growths arising "in the tubes themselves. It is quite possible that sewage thoroughly well settled "may give rise to fungoid growths, the detritus from which may cause suspended "matters to appear in a filtrate."

"The question of these growths and the circumstances which favour their "devolopment is one that should be further investigated."

164. As the use of percolating filters is likely to spread in the future, we are impressed with the need for practical experiments which have for their object either the prevention or the destruction of the growths on the surfaces of such filters.

That growths of this kind can be destroyed is shown by an experiment (suggested by Dr. Houston and Mr. Colin Frye) recently carried out on a small scale upon the surface of one of our experimental filters at Dorking. In March, 1907, the surface of this filter (which at that time treated septic tank liquor) was covered with a considerable layer of gelatinous growth, sufficient to cause local ponding in the tracks of the sprinkler jets. On March 16th the filter was rested for twenty-four hours in dry weather, and at the end of that time the surface was divided up into eight equal segments (1.6 square yards each), and seven of these were treated with the following reagents, the eighth segment being left untouched :—

(1) Powdered quicklime.
(2) Bleaching powder.
(3) A 20 per cent. solution of "Chloros."
(4) A 20 per cent. solution of copper sulphate
(5) A 20 per cent. solution of ferrous sulphate.
(6) A 20 per cent. solution of caustic soda.
(7) A 20 per cent. solution of sulphuric acid.

In the case of (1) and (2), sufficient of the dry solid was used to cover the surface with a fine layer of powder, while in the case of the other five segments one litre of each solution was applied to the material with a brush, the filter being then left resting for a further period of twenty-four hours.

At the end of this time, the segment which had been treated with caustic soda had undergone a distinct change in appearance, the clinker being perfectly clean on the upper side, though the under side was still covered with a slimy layer of half-dissolved growth. Of the other six segments, none showed any marked destruction of the growth, but the copper and iron sulphates had stained their segments green and rusty brown respectively. The filter was started again at 3 p.m. on the same day. A very large quantity of coarse brown solid matter (20 to 30 parts per 100,000) came away in the filter effluent during the first hour, but the quantity gradually decreased to about 6

parts per 100,000 after 24 hours. The samples taken during the first hour went putrid upon incubation, this being no doubt chiefly due to the outflush of solids, but otherwise the working of the filter was not seriously upset, though the nitric nitrogen in the effluent fell from 2 parts to 1 part per 100,000 for some days, eventually rising again to 2 parts on March 25th.

On April 22nd there were again signs of local ponding on the surface of the filter, but the growth on that segment which had been treated with caustic soda was considerably less than on the other segments. It was therefore thought desirable to try the application of a 20 per cent. solution of caustic soda to the whole surface of the filter. This was accordingly done, two gallons of the solution being used for the purpose. The procedure otherwise, *i.e.*, as regards the resting of the filter, was exactly the same as in the first experiment.

On the following morning the surface of the clinker was covered with a white deposit of sodium carbonate, and, on re-starting the filters shortly afterwards, a great quantity of dark brown solid matter came away in the effluent. Samples of effluent drawn for the first two hours readily putrified upon incubation. After twenty-four hours the effluent when freed from solid matter was normal, but a large quantity of suspended solids continued to come away with the effluent for about a week.

As in the case of the first experiment, the working of the filter, apart from the flush-out of solids, was not seriously upset, and after the first two hours from the restart there was no fall in the figure for oxidised nitrogen.

The exposed surface of the clinker was completely cleaned by this application of caustic soda solution, though a considerable amount of growth still adhered to the under side of the larger pieces of material. All ponding, however, disappeared, and no further growth of any consequence made its appearance for some months. The cost of the treatment, including labour, was 2½d. per square yard, but this would no doubt be materially reduced when carried out on a large scale.

Probably three such applications of 20 per cent. caustic soda would be necessary to keep the growth down during the winter or early spring months on the filter at Dorking.

165. Generally speaking growths do not appear to flourish on the surface of percolating filters constructed of fine material, but whether this is due to the size of the material or to the fact that filters of fine material are usually fed intermittently, we cannot say. Colonel Harding and Mr. Harrison, in an experiment at Leeds, found that they could keep down growth on a coarse-grained filter by substituting an intermittent sprinkler for a continuous one.

Our experiments seem to indicate that growths flourish most on filters treating precipitation liquor. This suggests that the use of chemicals (especially soluble sulphates) may influence their development, but, on the other hand, precipitation liquor usually contains considerably less suspended matter than other tank liquors, and a larger volume of it is for this reason generally treated per cube yard.

As regards the growths in channels along which effluents flow, they seem to require, for their development, an aerated but still unpurified sewage liquid, and it is possibly for this reason that they are generally more abundant in channels conveying dilute sewage liquids than in channels conveying strong sewage liquids, especially if the suspended matter is removed.

Some Observations as to the Relative Cost of Contact Beds and Percolating Filters.

166. On pages 36–43 of this Report we have made some observations on the relative cost and efficiency of preliminary processes for the removal of suspended matters from sewage, and we propose here to make a similar comparison between the two types of artificial filter usually adopted for the further purification of the sewage, and commonly known as "contact beds" and "percolating filters." As in the case of the preliminary processes, the cost of filters necessarily varies with local conditions, and no figures can be given which would be generally applicable. Following the plan adopted in the case of the preliminary processes, however, we propose to compare the two types of filters in a hypothetical case in which we assume :—

That ample fall is available ;

That the sewage is of a normal domestic character and of average strength ; *i.e.*, a sewage which would require about 100 parts of oxygen,* by weight, for the oxidation of the organic matter contained in 100,000 parts of sewage ;

That the flow of sewage is 1,000,000 gallons per day in dry weather ;

That in times of storm twice the dry weather flow is passed through the filters.

For the purpose of this comparison, we assume that the sewage has been subjected to preliminary tank treatment for the removal of suspended matter, and that in each case a satisfactory final effluent is to be produced.

We have not considered it necessary to compare the costs of all the modifications of percolating filters and contact beds of which there are examples, but have confined our comparion to percolating filters of coarse material, nine feet deep, and contact beds composed, for the most part, of medium-sized material, but having rather coarse material round the drains and a layer of fine material on the surface.

Mr. G. B. Kershaw, our Engineer, has prepared detailed drawings of the two kinds of filter, when used in conjunction with each of five different tank treatments, and, from these drawings has taken out quantities. The filters are all assumed to have been constructed on the same basis. The concrete flooring for the percolating filters, for example, has been assumed to be practically the same thickness as the concrete flooring for the contact beds, and the cost of concrete has been taken at a fixed price throughout. The class of work has been taken to be of the best kind, the walls and the floors of the contact beds, for instance, being made thoroughly water-tight by rendering with cement. It is due mainly to this fact that our estimates for the cost of contact beds are high. At some places a cheaper form of construction than we have assumed has been adopted. At Burnley, for instance, no concrete was used, and the beds, which are 3 feet in depth, cost approximately £1,300 per acre. At Manchester, where concrete was used, but where no rendering was done, the cost amounted to between £2,500 and £3,000 per acre for beds of the same depth. In Mr. Kershaw's estimates, the cost is about £5,700 per acre.

167. The working capacities of both contact beds and percolating filters depend to a large extent upon the strength of the liquor passed on to them and the amount of suspended matter contained in such liquor. In the following table, the strength of the tank liquor which is produced from our hypothetical sewage by each of the five preliminary processes, the amount of suspended matter in the liquor in each case, and the rate of filtration in each type of filter, are given :—

* This would generally be equivalent to about 10 or 12 parts per 100,000 of "oxygen absorbed" in four hours from strong permanganate.

Preliminary Process.	Strength of Tank Liquor, stated in parts by weight of oxygen per 100,000 required for the oxidation of the organic matter.	Amount of Suspended Matter in Tank Liquor (parts per 100,000).	*Contact Beds.		*Percolating Filters.	
			Rate of Filtration per cube yard per day (dry weather flow).	Cubic Content of Filtering Material required to treat one million gallons per day (dry weather flow).	Rate of Filtration per cube yard per day (dry weather flow).	Cubic Content of Filtering Material required to treat one million gallons per day. (dry weather flow).
			Gallons.	Cubic yards.	Gallons.	Cubic yards.
Quiescent settlement, with chemicals.†	50	1 to 4	140	7,143	175	5,714
Continuous flow settlement, with chemicals.	60	3 to 6	85	11,765	150	6,666
Quiescent settlement, without chemicals.	70	5 to 8	55	18,182	100–125	8,928
Continuous flow settlement, without chemicals.	80	10 to 15	40	25,000	75–100	11,494
Septic tanks - - -	80	10 to 15	40	25,000	75–100	11,494

Initial Cost of Contact Beds and Percolating Filters.

168. The following table gives Mr. Kershaw's estimates of the constructional cost of percolating filters and contact beds required to treat a dry weather flow of 1,000,000 gallons per day of our hypothetical sewage on the above basis. The estimates include the sum of 15 per cent. for engineering and contingencies.

Preliminary Process.	Contact Beds.	Percolating Filters.
	£	£
Quiescent settlement, with chemicals - - - -	8,527	7,376
Continuous flow settlement, with chemicals - - -	14,898	8,836
Quiescent settlement, without chemicals - - - -	22,080	10,596
Continuous flow settlement, without chemicals - -	26,846	13,824
Septic tanks - - - - - - - - - -	26,846	13,824

The principal items in the estimates for both kinds of filters are: filtering medium, concrete in walls and floors and rendering; and excavation in the case of the contact beds.

The figures for these items are given in the following tables:—

Contact Beds.

Preliminary Process.	Cost of Filtering Medium.	Cost of Concrete in Floors and Walls.	Cost of Rendering.	Cost of Excavation.
	£	£	£	£
Quiescent settlement, with chemicals - -	3,777	2,545	675	Single set of beds; very little excavation. ‡
Continuous flow settlement, with chemicals -	3,545	3,882	1,350	885
Quiescent settlement, without chemicals - -	5,431	5,461	1,650	1,204
Continuous flow settlement, without chemicals.	7,231	7,038	2,171	1,722
Septic tanks - - - - - -	7,231	7,038	2,171	1,722

* The quality of the effluents produced by the ten plants would, of necessity, not be identical. The average quality as expressed in terms of oxidizability of effluent (see paragraphs 178 and 179) would be something like +2 for the double contact effluents and—2 for the percolation effluents.

† In the case of quiescent settlement with chemicals, we have allowed for single contact only; in the other cases, for double contact.

‡ We have assumed in our hypothetical case that the primary beds are practically out of ground, and that excavation is required only in the case of the secondary beds.

Percolating Filters.

Preliminary Process.	Cost of Filtering Medium.	Cost of Concrete in Floors and Walls.	Cost of Rendering.
	£	£	£
Quiescent settlement, with chemicals	1,951	2,617	269
Continuous flow settlement, with chemical	2,431	3,271	336
Quiescent settlement, without chemicals	4,375	5,889	605
Continuous flow settlement, without chemicals	5,833	7,851	806
Septic tanks	5,833	7,851	806

Effluent Settling Tank.

169. In our hypothetical case, a tank is provided for the settlement of the effluent from the contact beds, as well as from the percolating filters. Some means are needed in the case of coarse percolating filters for the settlement of the effluent solids; and in the case of the contact beds we have assumed that a tank was required for the purpose of rendering the discharged liquid uniform in quality, and thus preventing the possible discharge of a putrescible effluent during the first flush, and, more especially, of putrescible solids. The effluent tank is of the Dortmund type, having a capacity of about 84,000 gallons, so as to provide for a stay in the tank of about two hours in each case. The total cost of this tank is calculated to be £682.

Loan Charges.

170. The following table gives the area and the assumed cost of the land occupied by the installations.

We have taken the price of land throughout at £100 per acre.

Preliminary Process.	Contact Beds.		Percolating Filters.	
	Land required (acres).	Cost of Land.	Land required (acres).	Cost of Land.
		£		£ s. d.
Quiescent settlement, with chemicals	1·26	126	0·73	73 0 0
Continuous flow settlement, with chemicals	2·03	203	0·91	91 0 0
Quiescent settlement, without chemicals	3·21	321	1·095	109 10 0
Continuous flow settlement, without chemicals	4·18	418	1·46	146 0 0
Septic tanks	4·18	418	1·46	146 0 0

Assuming that the loan is raised at 3½ per cent. interest per annum, and is repayable in equal annual instalments over a period of thirty years, the annual loan charges on the complete installations would be as follows :—

Preliminary Process.	Contact Beds.		Percolating Filters.	
	Loan charges in respect of Contact Bed Installation.		Loan charges in respect of Percolating Filter Installation including charges in respect of sprinklers.	
	Per annum.	Per million gallons (dry weather flow).	Per annum.	Per million gallons (dry weather flow).
	£ s. d.	£ s. d.	£ s. d.	£ s. d.
Quiescent settlement, with chemicals	507 3 9	1 7 10	470 19 7	1 5 10
Continuous flow settlement, with chemicals	858 4 0	2 7 0	558 11 3	1 10 7
Quiescent settlement, without chemicals	1,255 2 9	3 8 9	662 9 2	1 16 3
Continuous flow settlement, without chemicals	1,519 6 3	4 3 3	854 8 5	2 6 10
Septic tanks	1,519 6 3	4 3 3	854 8 5	2 6 10

Labour and Supervision.

171. For the contact bed installations, we assume that the services of two men (one for the day and one for the night) would be required, and for the percolating filter installations, the services of one man.

Taking the labourer's time at 21s. a week, and including one-third of the manager's time at a salary of £130 per annum (say, £43), the cost of labour and supervision in connection with the installations would be as follows :—

Preliminary Process.	Contact Beds.		Percolating Filters.	
	Per annum.	Per million gallons (dry weather flow).	Per annum.	Per million gallons (dry weather flow).
	£	s. d.	£	s. d.
Quiescent settlement, with chemicals	152	8 4	98	5 4½
Continuous flow settlement, with chemicals	152	8 4	98	5 4½
Quiescent settlement, without chemicals	152	8 4	98	5 4½
Continuous flow settlement, without chemicals	152	8 4	98	5 4½
Septic tanks	152	8 4	98	5 4½

Cost of washing and renewing Filtering Medium.

Contact Beds.

172. According to the evidence, which is dealt with in another part of this Report, we find that the average cost of removing, washing, replacing, and making good the material of a contact bed, by machinery, is about 1s. 6½d. per cube yard, exclusive of cost of washing plant.

In the present calculations we assume that the cost per cube yard of washing, etc., is 1s. 7d., and that the material in the primary beds would require washing every four years, and that in the secondary beds every ten years.

On these assumptions, one acre of primary beds, 3 feet deep, would cost £383 every four years for washing and renewal, or about £96 per annum ; and one acre of the secondary beds, £383 every ten years, or £38 6s. per annum.

Percolating Filters.

173. So far as our experience of percolating filters of coarse material has gone, we think it may be taken that the material of these filters will last for a very long period of time, if a few inches on the top of the filter are removed and renewed occasionally. At Accrington, Rochdale, and York, beds of this kind, constructed both of coke and clinker, have been in constant use for eight years. At Horfield a clinker bed, dismantled after five years' use, was found to be in almost the same condition as when it was started. We do not propose, therefore, to add anything to the cost of our percolating filter installations for washing and renewal of material.

Plant special to Percolating Filters.

174. We have assumed that the life of rotary sprinklers treating domestic sewage is ten years, and have therefore calculated the loan charges on this period.

At Accrington the annual cost of repairs to an automatic rotary sprinkler, taken over a period of three years, was found to average 18s. 4d. In our calculations, we have taken the cost of repairs at £1 per sprinkler per annum.

The following table shows our estimates of the cost of washing contact bed material. and, in regard to percolating filters, the sums required for repairs and loan charges in respect of sprinklers :—

Preliminary Process.	Contact Beds.		Percolating Filters.			
	Annual Charges in respect of Washing and Renewal of Beds.	Cost per million gallons in respect of Washing and Renewal of Beds.	Annual Loan Charges in respect of Sprinklers based on a ten year period.	Loan Charges in respect of Sprinklers per million gallons (dry weather flow).	Annual Cost of Repairs to Sprinklers.	Cost of Repairs to Sprinklers per million gallons (dry weather flow).
	£ s. d.	s. d	£ s. d.	s. d.	£	d.
Quiescent settlement, with chemicals.	141 2 5	7 9	28 17 2	1 7	4	$2\frac{1}{2}$
Continuous flow settlement, with chemicals.	169 8 6	9 3	36 1 6	2 0	5	$3\frac{1}{4}$
Quiescent settlement, without chemicals.	266 10 1	14 7	43 5 9	2 $4\frac{1}{2}$	6	$3\frac{3}{4}$
Continuous flow settlement, without chemicals.	360 18 4	19 9	57 14 5	3 2	8	$5\frac{1}{4}$
Septic tanks - - -	360 18 4	19 9	57 14 5	3 2	8	$5\frac{1}{4}$

Total Cost for Filtration alone.

175. The total cost of the contact bed and percolating filter installations, including loan charges, labour and supervision, etc., according to the foregoing calculations, would be as follows :—

Preliminary Process.	Contact Beds.		Percolating Filters.	
	Per Annum.	Per Million Gallons (dry weather flow).	Per Annum.	Per Million Gallons (dry weather flow).
	£ s. d.	£ s. d.	£ s. d.	£ s. d.

Septic tanks - - - - -	2,032 4 7	5 11 4	960 8 5	2 12 8

* Single contact assumed in this case.

Total Cost of Complete Treatment.

176. The total cost of each of the preliminary processes has been shown in another part of this Report. Adding this to each of the filtration processes, we arrive at the following figures for the total cost of the complete treatment of a dry weather flow of 1,000,000 gallons of sewage per day.

Per Annum.

Preliminary Process.	Contact Beds.			Percolating Filters.		
	Total Cost of Preliminary Treatment.	Total Cost of Filtration Process.	Total Cost of Complete Treatment.	Total Cost of Preliminary Treatment.	Total Cost of Filtration Process.	Total Cost of Comp'ete Treatment.

177. On the basis which we have adopted, purification of sewage (after preliminary treatment) by means of percolating filters costs only about two-thirds as much as purification by double contact beds.

Where, however, the sewage has first been subjected to quiescent settlement, with chemicals, and single contact is sufficient to produce a satisfactory effluent, the cost becomes more nearly equal, though percolating filters are, even in that case, slightly cheaper.

The cost depends, of course, very largely on the kind of construction adopted.

Our estimates for the cost of double contact beds per acre, 3 feet deep, including filtering material, concrete, rendering, drains, distribution channels, engineering and contingencies, etc., amount approximately to £5,700 per acre. If the beds were built by simple excavation and banking, as is permissible in heavy clay soil, the cost would be very considerably reduced.

We have taken the price of filtering material at 6s. per cube yard, placed in position in the beds, which may be considered a fair average, though evidence shows the price has in some cases been much lower. Since this item alone amounts to about £1,396 per acre, 3 feet deep, it is at once apparent how largely the price of filtering material influences the cost of treatment.

* Single contact assumed in this case.

RELATIVE EFFICIENCY OF CONTACT BEDS AND PERCOLATING FILTERS.

178. Sewages vary in composition, not only in regard to the degree of dilution to which they are naturally subjected, but also in regard to the proportion in which different kinds of organic matter are present in them, and we are not aware of any really accurate method by which the work done by different filters, treating different sewages, can be compared.

We have, however, found it convenient to adopt, for the purpose of comparing the results obtained at different places, a unit of purification, which is based on the oxidizability of the sewage and the oxidizability of the filtrate, after giving credit for the oxygen contained in the effluent in the form of nitrate.

This basis for a unit was suggested by Dr. McGowan.

The unit of time we have taken as 24 hours, the unit of quantity as 1 gallon, and the unit of filtering material as 1 cubic yard.

Thus, to express the number of units of purification effected by a filter, we have deducted the number of parts by weight of oxygen taken up by 100,000 parts of the effluent from the filter, from the number of parts by weight of oxygen taken up by 100,000 parts of the liquor going on to the filter. The figure so obtained has been multiplied by the number of gallons of liquor, per cube yard, passing through the filter in 24 hours.

179. In his Memorandum* on the measurement of the strength of sewage, Dr. McGowan has set out reasons for adopting a formula, by which the figure representing the number of parts of oxygen which the sewage will take up can be calculated, with a fair degree of accuracy.

For the purpose of ascertaining the number of parts of oxygen which an effluent will take up, Dr. McGowan has also suggested that, in lieu of carrying out the actual experiment of keeping an effluent until it has become completely oxidized, and actually measuring the amount of oxygen taken up, the amount may be approximately arrived at by a calculation based on other figures of analysis. The formula which he suggests is:

(Ammoniacal *N.* + Organic *N.*) × 4·5 + Volatile matter of suspended solids × 2 – Nitric Nitrogen × 3.

As regards this formula, it is well known that the better an effluent is oxidized, the less change will it undergo on keeping. The work of Dr. Adeney and others has shown that, in the case of good effluents, the figure for organic nitrogen would represent, for the most part, organic matter which had undergone fermentation, and in considering the *quality* of such effluents, e.g., with reference to their effect on streams, we think the figure may generally be neglected.

It is, however, open to question whether, in calculating the work done by a filter, it is not better to include the figure inasmuch as the whole of the organic nitrogen of liquor going on to the filter has been taken into account in calculating, by the empirical formula given on page 16, the strength or oxidizability of that liquor.

The point is further discussed in the report by Dr. McGowan and Mr. Colin Frye on the estimation of work done by filters which is contained in Appendix IV.

Until the calculation method has been compared with the results of direct experiment in a large number of cases, no precise statement as to its value can be made, but we have found it convenient to adopt it in the preparation of this Report.

On this basis the following table has been compiled showing the units of purification effected by the filters at the places indicated.

* Appendix IV.

TABLE SHOWING THE UNITS OF PURIFICATION EFFECTED BY FILTERS.

Place.	Process of Treatment.	Character of Filtering Material.	Amount treated per cube yard of filter per day.	Strength * of Liquor Treated (calculated).	* Strength ‡ of Filter Effluent (calculated).	General Quality of Effluent, as described by Dr. McGowan.	Units of Purification.
			Gallons.	Parts per 100,000	Parts per 100,000		
Chorley	Chemical precipitation and percolating filters	Very fine to coarse	500	50	0·9	Good	24,550§
Rochdale	Septic tank and percolating filters	Coarse	141	83	4·4	Good	11,125
Dorking (Experimental Works)	Chemical precipitation and percolating filters	,,	211	55·3	3·9	Very fair	10,845
Kingston-upon-Thames	Chemical precipitation and single contact beds	Medium to coarse	250	51	7·7	Good	10,825
York	Septic tank and percolating filters	Coarse	150	58	−3·5‡	Good, apart from solids	9,225
Accrington	,, ,, ,,	,,	140	94	28·4	Good, apart from solids	9,184
Dorking (Experimental Works)	Chemical precipitation and percolating filters	,,	175	53·5	3·5	Very fair	9,065
,,	Settlement tank and percolating filters	,,	120	80·1	8·8	Fair	8,556
,,	Septic tank and percolating filter	,,	120	81·6	11·2	Moderate	8,448
Normanton	Chemical precipitation and percolating filters	Very fine to coarse	98	92	10·0	Very fair	8,036
Birmingham	Septic tank and percolating filter	Medium to coarse	82½	113	20·2	Fair to good	7,656
Hampton	Triple contact beds	1st bed, coarse; 2nd bed, medium; 3rd bed, fine	43	172	−3·7‡	Good	7,555
Halton	Settlement tanks and double contact beds	Coarse	106	80	10·8	Indifferent	7,335
Hartley Wintney	Septic tank and percolating filter	Medium to fine	73	108	8·5	Moderate	7,264
Manchester	,, ,, ,,	Medium	77	106	15·0	Rather poor	7,007
Huddersfield	Septic tank and single contact beds	Coarse	110	77·1	16·4	Good, apart from solids	6,897
Dorking (Experimental Works)	Chemical precipitation and percolating filter	,,	120	68·8	18·1	Not very good	6,084
Hartley Wintney	Septic tanks and single contact beds	Medium to fine	73	108	27·3	Poor	5,871
Huddersfield	Septic tank and double contact beds	1st, coarse; 2nd, medium	76	77·1	3·1	Fair to good	5,624
Calverley	Chemical precipitation and single contact beds	Coarse to fine	60	124	33·2	Poor	5,448
Rochdale	Chemical precipitation and percolating filter	Coarse	157	39	5·7	Good, apart from solids	5,228
Guildford	Septic tank and percolating filter	,,	50	109·2	4·8	Good	5,220

Heywood	Chemical precipitation and single contact beds	Very fine to coarse	173	40·2	11·0	Evidently not very good	5,052
Caterham	Septic tank and percloating filter	Medium to coarse	31	161	14·0	Fair	4,557
Withnell	Chemical precipitation and percolating filters	Very fine to coarse	63½	81	9·3	Very fair	4,553
Andover	Septic tank and single contact bed	Medium to fine	115	90	50·5	Poor	4,543
Horfield	Chemical precipitation and percolating filter	Coarse	151	36	6·0	Very fair to good	4,530
Leeds	Percolating filter (Leeds filter)	Very coarse	52	123	36·7	Fair	4,488
,,	,, ,, (Ducat)	Medium	25	172·6	2·3	Very good	4,373
,,	Septic tank and percolating filter	Coarse	63	75·8	7·2	Good, apart from solids	4,322
,,	Septic tank and double contact bed	1st, fine to medium; 2nd, medium	45	92·4	– 3·1‡	Good	4,298
Guildford	Septic tank and percolating filter	Coarse	50	90·3	4·8	Good	4,275
Leeds	Double contact beds	1st, coarse; 2nd, medium	32	127	5·2	Moderate	3,998
Hendon	Percolating filter (Ducat)	Medium	40	107	7·9	Good, when settled	3,964
Maidstone	Double contact beds	1st beds, coarse; 2nd beds, fine	23·7	164	4·7	Moderate to fair	3,775
Exeter (Main Works)	Septic tank and single contact beds	Medium to coarse	55	99	31·2	Poor	3,729
Oswestry	Double contact beds	1st, medium to coarse; 2nd, medium	41	91	4·7	Fair	3,538
Sheffield	,, ,, ,,	Medium to fine	60	57·6	5·1	Good	3,150
Burnley	Septic tank and double contact beds	1st, coarse; 2nd, fine	40	74·1	– 1·0‡	Good	3,004
Withnell	Double contact beds	1st, coarse; 2nd, medium	18·2	174	25·3	Not satisfactory	2,706
Exeter (St. Leonard's)	Septic tank and single contact beds	Medium to fine	75	39	3·0	Fair	2,700
Guildford	Septic tank and double contact beds	1st, medium to coarse; 2nd, medium to fine	22·7	125	6·2	Moderate	2,697
Leeds	Settlement tank and percolating filter	Coarse	63	59·7	16·9	Good, apart from solids	2,696
,,	Chemical precipitation and percolating filter	,,	50	51·8	– 0·4‡	Good to very good	2,610
Oldham	Single contact beds	Medium to fine	73	51·1	15·7	Moderate	2,584
Little Drayton	Settlement tank and percolating filter	Medium	15·2	165	6·4	Good to fair	2,411
Withnell	Chemical precipitation and percolating filter	Very fine to coarse	63½	29·8	0	Good	1,892
Clifton	Settlement tank and percolating filter	,, ,,	15·6	123	5·8	Good to fair	1,828
Slaithwaite	Septic tank and single contact bed	Medium to coarse	62	35·6	6·3	Indifferent	1,817
Prestolee	Septic tank and percolating filter	Fine to coarse	46	22	0	*Very* good	1,012

* The strength of the liquor and filter effluent is expressed by the amount of oxygen required for the complete oxidization of its ammonia and organic matter. ‡ The minus sign which is placed against the figure representing the strength of certain effluents indicates that the oxygen present, in the form of nitrate, was, to the extent of the figure against which it is placed, more than sufficient to oxidize the organic matter in the effluent. § This figure is based on a volume of 500 gallons per cube yard per day—the actual rate at the time when the average samples were drawn. Probably about 400 gallons per cube yard per day is as much as the filters could continuously treat, and, on this basis, the number of units of purification would be rather under 20,000.

Accrington Experiments.

180. For the purpose of making an accurate comparison of the working power of contact beds and percolating filters treating the same sewage liquor, and also for comparing the treatment of strong and dilute tank liquors on each form of filter, we constructed an experimental plant at the Accrington Sewage Works.

The plant consisted of two pairs of exactly similar contact beds, 3 feet deep, and two exactly similar percolating filters, of rather coarse material, each 6 feet deep.

The cubic contents of each percolating filter was equal to that of each pair of contact beds.

The details of these experiments are set out in a Memorandum by Dr. McGowan and Mr. Colin Frye, contained in Appendix IV.

The experiments were carried out with great care, both on the spot and in the laboratory, and the results may be regarded as quantitative comparative results, from which we think useful generalisations may be drawn.

For the construction of the filters we are greatly indebted to Mr. W. J. Newton, the Surveyor to the Accrington and Church Sewage Board, while Mr. J. Boothman, the Chemist in charge at the outfall works, has controlled their daily working. The delicate adjustment of the dilutions of the tank liquor, upon which the whole value of the experiments depends, has been carried out by Mr. Boothman with the greatest care and skill, and with consistent success.

The liquor treated throughout has been the Accrington septic tank liquor, either by itself or diluted with water.

Our intention had been to treat at the same rate on the percolating filters and the contact beds, but as will be seen, it was not practicable to do this.

181. There were five experiments in all, as follows :—

Experiment I.—Comparative treatment on percolating filters and contact beds of (*a*) 100 gallons per cube yard per 24 hours of septic tank liquor and (*b*) 100 gallons of septic tank liquor + 100 gallons of water = 200 gallons of weak liquor.

The *actual average* rates of filtration on the two pairs of contact beds were 72·2 and 148·8 gallons per cube yard per day, respectively, the beds treating strong liquor being filled twice a day and those treating weak liquor four times a day. Broadly speaking, therefore, the contact beds only treated in this experiment three-fourths of the volumes treated by the percolating filters. This was owing partly to the original water capacity being less than 100 gallons per cube yard, and partly to their gradual loss of capacity. At the commencement of the experiment two fillings per day on the pair of contact beds treating strong liquor were equivalent to 90 gallons per cube yard, and four fillings per day on the pair treating weak liquor were equivalent to 179 gallons.

Duration of experiment :—May 5th, 1905, to June 30th, 1906.

Experiment II.—Comparative treatment on percolating filters and contact beds of (*a*) 100 gallons per cube yard per 24 hours of septic tank liquor and (*b*) of 50 gallons of septic tank liquor + 50 gallons of water = 100 gallons of weak liquor.

The *actual average* rates on the contact beds were 51·6 and 57·9 gallons per cube yard per day, respectively,

Duration of experiment : July 2nd, 1906, to March 23rd, 1907.

Experiment III.—Comparative treatment on percolating filters *alone* of (*a*) 125 gallons per cube yard per 24 hours of septic tank liquor and (*b*) 125 gallons of septic tank liquor + 125 gallons of water = 250 gallons of weak liquor.

Duration of experiment :—April 8th to June 7th, 1907.

Experiment IV.—Comparative treatment on percolating filters alone of (*a*) 200 gallons per cube yard per 24 hours of septic tank liquor ; and (*b*) 200 gallons of septic tank liquor+200 gallons of water=400 gallons of weak liquor.

Duration of experiment :—June 10th to October 26th, 1907.

Experiment V.—Comparative treatment on percolating filters alone of (*a*) 250 gallons per cube yard per 24 hours of septic tank liquor ; and (*b*) 250 gallons of septic tank liquor +250 gallons of water=500 gallons of weak liquor.

Duration of experiment :—October 28th, 1907, to June 18th, 1908.

The main object of these last three experiments, besides the further comparison between the purification of the two liquors, was to see how much these filters can actually treat, with the production of a good effluent.

The following is a general summary of the results of these experiments :—

182. *Accrington Experiment I.*—The percolating filters of coarse material effected practically the same amount of purification, whether they were treating 100 gallons per cube yard of undiluted septic tank liquor, or 200 gallons per cube yard of a liquor of half the strength, the total organic impurity going on to the filters being the same in both cases.

The primary contact bed, when the pair of beds were treating about 150 gallons of weak liquor per cube yard per day, gave rather better results than the primary bed of the pair treating strong liquor at half this rate, and the same is true, in each case, of the secondary beds. So long, therefore, as care is taken to avoid water-logging, *i.e.*, to give the beds sufficient time to drain and aerate, it is rather easier to treat upon contact beds two volumes of weak liquor than one volume of strong liquor.

During the fourteen months over which this experiment extended, the percolating filters treating strong liquor did one and a half times as much work as the contact beds treating strong liquor, while the percolating filters treating weak liquor did one and a third times as much work as the contact beds treating weak liquor.

The units* of purification were as follows :—

	Units of Purification per cube yard.
Percolating filter treating strong tank liquor - -	7,310
Double contact beds treating strong tank liquor -	5,011
Percolating filter treating weak tank liquor - -	7,678
Double contact beds treating weak tank liquor - -	5,803

As regards the quality of the two strong liquor effluents, *suspended solids included*, the results were slightly in favour of the percolating filter effluent, which still required 12 parts of oxygen per 100,000 for its complete oxidation, while the contact bed effluent required 16 parts. If we *eliminate the solids* in both cases, the oxidizability of the liquid alone would be approximately represented by 2 parts of oxygen in the case of the percolating filter effluent, and 8 parts in the case of the contact bed effluent. This superiority of the percolating filter effluent, so far as lesser oxidizability is concerned, was partly due to the fact that it contained 2·4 parts of nitric (plus nitrous) nitrogen, as against 1 part in the contact bed effluent ; but even apart from this, it was rather the better, the actual oxidizable matter left in the liquid being equivalent to about 8·5 parts of oxygen, while that in the contact bed effluent was equivalent to about 10 parts.

In the case of the two weak liquor effluents, suspended solids included, the results were in favour of the double contact bed effluent, which only required 4 parts of oxygen for its complete oxidation, as against 9·5 parts for the percolating filter effluent. If we eliminate the solids, there was practically no difference in the quality of the two effluents, both of them being well oxidized. If both solids and nitrate are eliminated, the double contact bed effluent is again rather the better, with an oxidizability figure of 4, as against 6·5 for the percolating filter effluent.

The above figures may be tabulated as follows :—

	Effluents from Strong Tank Liquor.		Effluents from Weak Tank Liquor.	
	Percolation.	Double Contact.	Percolation.	Double Contact.
† Oxidizability of whole effluent, including solids and giving credit for nitrate - - -	*Parts of* 12	*oxygen per* 16	100,000 *parts* 9·5	*of effluent.* 4·0
Oxidizability of effluent, without its suspended solids, and giving credit for nitrate - -	2	8	2·0	2·0 ap.
Oxidizability of effluent, without solids, and giving no credit for nitrate - - - - -	8·5	10	6·5	4·0

* The units of purification are calculated on the basis indicated on page 107 of this Report.

† Oxidizability calculated on the formula suggested by Dr. McGowan (*see* paragraph 179, page 107).

The quality of the effluents *without their suspended solids*, as regards taking up of dissolved oxygen in 24 hours and incubation, is shown by the following figures:—

Parts per 100,000.

	Effluents from Strong Tank Liquor.		Effluents from Weak Tank Liquor.	
	Percolation.	Double Contact.	Percolation.	Double Contact.
Dissolved oxygen taken up from water in 24 hours at about 18° C. (65° F.)	0·30 (22) 0·37 (12)	0·61 (11)	0·28 (21) 0·30 (11)	0·31 (10)
Incubation (by smell)	All passed (25).	All passed (11).	All passed (21).	All passed (10).

Figures in brackets represent number of estimations.

183. *Accrington Experiment II.*—In the comparative treatment, *upon the percolating filters of coarse material*, of 100 gallons of strong and 100 gallons of weak tank liquor, respectively, nothing was gained in purity of effluent by giving the filter treating the weak liquor only half the work to do; this filter was merely working much under its real power.

It was noteworthy that in Experiments I. and II. the actual efficiency of the contact beds (treating both strong and weak tank liquor), as regards work done per cube yard, remained the same throughout. In both experiments about two-thirds of the impurity of the septic tank liquor was removed by the primary bed, whether strong or weak liquor was being treated.

In Experiment II., which lasted for eight months, the percolating filter treating 100 gallons per cube yard of strong liquor did more than twice as much actual work as the double contact beds treating 51·6 gallons with two fillings per day; the reason for this increasing difference in work done, as compared with Experiment I., was the gradual loss of capacity in the contact beds.

The units of purification in Experiment II. were as follows:—

	Units of Purification per cube yard.
Percolating filter treating strong tank liquor	8,440
Double contact beds treating strong tank liquor	3,576
Percolating filter treating weak tank liquor	4,120
Double contact beds treating weak tank liquor	2,200

The quality of the effluents was as follows:—

	Effluents from Strong Tank Liquor.		Effluents from Weak Tank Liquor.	
	Percolation.	Double Contact.	Percolation.	Double Contact.
	Parts of oxygen per 100,000 *parts of effluent.*			
Oxidizability of whole effluent including solids, and giving credit for nitrate	−3·2	14·0	−0·7	4·2
Oxidizability of effluent, without its suspended solids and giving credit for nitrate	−6·2	5·8	−3·3	0·2
Oxidizability of effluent, without solids and giving no credit for nitrate	3·6	7·7	2·4	3·2

NOTE.—The minus sign indicates that the oxygen present, in the form of nitrate, was, to the extent of the figure against which it is placed, more than sufficient to oxidize the organic matter in the effluent.

The quality of the effluents—*without their suspended solids*—as regards taking up of dissolved oxygen and incubation, is shown by the following figures :—

	Effluents from Strong Tank Liquor.		Effluents from Weak Tank Liquor.	
	Percolation.	Double Contact.	Percolation.	Double Contact.
		Parts per 100,000.		
Dissolved oxygen taken up from water in 24 hours at about 18° C.	0·03 (4)	0·12 (4)	0·07 (4)	0·10 (4)
Dissolved oxygen taken up from water in 5 or 6 days	0·43 (3)	1·70 (3)	0·33 (4)	1·0 ap. (3)
Incubation (by smell)	All passed (8)	All passed (8)	All passed (8)	All passed (8)

The capacities of the contact beds were as follows :—

	At beginning of Experiment, July 2nd, 1906.	At end of Experiment, February 18th, 1907.	Loss of capacity in Gallons.	Percentage loss of water capacity.
	gallons.	gallons.		
Primary bed treating strong tank liquor	735	640	95	8 per cent.
Secondary bed treating strong tank liquor	1,030	970	60	6 „
Primary bed treating weak tank liquor	780	750	30	3 „
Secondary bed treating weak tank liquor	950	890	60	6 „

As already stated, the actual volumes of liquid treated per cube yard per twenty-four hours throughout Experiment II. were :—

Percolating filter treating strong tank liquor - 100 gallons.
Double contact beds treating strong tank liquor - 51·6 „
Percolating filter treating weak tank liquor - 100 „
Double contact beds treating weak tank liquor - 57·9 „

The contact beds thus treated only about half as much liquor, in both cases, as the percolating filters.

184. *Accrington Experiment III.*—In this experiment, which lasted from April 8th to June 7th, 1907, the percolating filter treating strong liquor received 125 gallons per cube yard per day and that receiving weak liquor 250 gallons per cube yard per day. It was thus similar to Experiment I, but with an increased dose in the case of both filters, the object being to see how much the filters could actually treat with efficiency. Owing to the wet season, however, the strength of the liquors in this last experiment was less than in Experiments I and II, thus :—

	Calculated Strength.	Suspended Solids.
Strong tank liquor	73·2	20·1
Weak tank liquor	40·7	10·3

The suspended solids in the filter effluents were rather high, on account of the "spring out-flush." *

The purification obtained was as follows :—

	Units of Purification per cube yard.
Percolating filter treating strong tank liquor	8,050
Percolating filter treating weak tank liquor	9,225

* As is now well known, large quantities of suspended solids usually come out in the effluent from a percolating filter of coarse material in the late spring, with the advent of the warmer weather. This appears to be due to the development of worms, larvæ, etc., in the interior of the filter at this time. The same thing has been observed, though in lesser degree, in the case of percolating filters of fine material and also contact beds.

The quality of the two effluents is shown by the following figures :—

	Effluents from Strong Tank Liquor.	Effluents from Weak Tank Liquor.
	Parts of oxygen per 100,000 parts of effluent.	
Oxidizability of whole effluent, including solids and giving credit for nitrate.	8·8	3·8
Oxidizability of effluent, without its suspended solids and giving credit for nitrate.	– 2·2*	– 1·4*
Oxidizability of effluent, without solids and giving no credit for nitrate.	4·8	2·7

The quality of the effluents—*without their suspended solids*, as regards taking up of dissolved oxygen and incubation—is shown by the following figures :—

	Effluent from Strong Tank Liquor.	Effluent from Weak Tank Liquor.
Dissolved oxygen taken up from water in 5 days at 18° C. -	0·62 (5)	0·84 (5)
Incubation (by smell) - - - - - - - - -	All passed (5)	All passed (5)

Both effluents were therefore very good, and, apart from their suspended solids, there was practically nothing to choose between them. It will be noted that the filter treating weak liquor was receiving a liquor a little more than half as strong as the other (calculated strength—40·7, as against 73·2 for the strong liquor).

Owing to the strong liquor being less concentrated in this experiment than in the two preceding ones, the actual work done on the filter treating strong liquor was only 8,050 units per cube yard per 24 hours, but in the case of the filter treating weak liquor it was 9,225 units.

185. *Accrington Experiment IV.*—In this experiment, which lasted from June 10th to October 26th, 1907, the percolating filter treating strong liquor received 200 gallons per cube yard per day, and that receiving weak liquor 400 gallons per cube yard per day. It was thus similar to Experiments I. and III., but with a further increased dose in the case of both filters. The calculated strengths of the tank liquors in this experiment were almost the same as in the preceding one, but the suspended solids were less in amount, thus :—

	Calculated Strength.	Suspended Solids.
Strong tank liquor - - - - - - - - - -	74·1	13·5
Weak tank liquor - - - - - - - - - -	39·6	6·3

The weak liquor filter was again treating a liquor which was *rather more* than half as strong as the other.

The purification obtained was as follows :—

	Units of Purification per Cube Yard.
Percolating filter treating strong tank liquor - - - -	14,300
Percolating filter treating weak tank liquor - - - -	15,160

The quality of the two effluents is shown by the following figures :—

	Effluents from Strong Tank Liquor.	Effluents from Weak Tank Liquor.
	Parts of oxygen per 100,000 parts of effluent.	
Oxidizability of whole effluent, including solids and giving credit for nitrate - - - - - - - - - -	2·6	1·7
Oxidizability of effluent, without its suspended solids and giving credit for nitrate - - - - - - - - -	– 3·8*	– 3·1*
Oxidizability of effluent, without solids and giving no credit for nitrate - - - - - - - - - -	4·4	2·3

* The minus sign indicates that the oxygen present, in the form of nitrate, was, to the extent of the figure against which it is placed, more than sufficient to oxidize the organic matter in the effluent.

The quality of the effluents—*without their suspended solids*, as regards taking up of dissolved oxygen and incubation—is shown by the following figures :—

	Effluent from Strong Tank Liquor.	Effluent from Weak Tank Liquor.
Dissolved oxygen taken up from water in five days at 18°C. -	0·56 (9)	0·49 (9)
Incubation (by smell) - - - - - - - - - -	All passed (9)	All passed (9)

Here, again, both effluents were well oxidized and good, and there was little to choose between them. If anything, they were rather better oxidized than the corresponding effluents in Experiment III. (notwithstanding the lesser volumes treated in that case), as judged by the dissolved oxygen taken up by the paper-filtered effluents in five days. This was probably due to the fact that more of the warm summer months were included in Experiment IV.; and that the spring out-flush of solids took place during Experiment III.

The work done on the filter treating strong liquor was 14,300 units, and on the filter treating weak liquor 15,160 units.

186. *Accrington Experiment V.*—In this final experiment, which lasted from October 28th, 1907, to June 18th, 1908, the percolating filter treating strong liquor received 250 gallons per cube yard per day, and that receiving weak liquor 500 gallons per cube yard per day. The calculated strengths of the liquors treated were a little less than in Experiment IV., though suspended solids were present in rather larger amount, thus :—

	Calculated Strength.	Suspended Solids.
Strong tank liquor - - - - - - - - - -	69·4	14·4
Weak tank liquor - - - - - - - - - -	37·0	7·4

As before, the weak liquor filter was treating a liquor which was fully half as strong as the other.

The purification obtained was as follows :—

	Units of Purification per cube yard.
Percolating filter treating strong tank liquor - - - - -	12,425
Percolating filter treating weak tank liquor - - - - -	14,600

The quality of the two effluents is shown by the following figures :—

	Effluents from Strong Tank Liquor.	Effluents from Weak Tank Liquor.
	Parts of oxygen per 100,000 parts of effluent.	
Oxidizability of whole effluent, including solids and giving credit for nitrate - - - - - - - -	19·7	7·8
Oxidizability of effluent, without its suspended solids and giving credit for nitrate - - - - - -	7·1	2·2
Oxidizability of effluent, without solids and giving no credit for nitrate - - - - - - - - - -	10·8	5·0

The quality of the effluents—*without their suspended solids*, as regards taking up of dissolved oxygen and incubation—is shown by the following figures :—

	Effluent from Strong Tank Liquor.	Effluent from Weak Tank Liquor.
Dissolved oxygen taken up from water in five days at 18°C. -	2·31 (13)	1·16 (13)
Incubation (by smell) - - - - - - - - - -	{ 11 passed / 2 failed (13) }	All passed (13)

The effluents in Experiment V. thus show a marked falling off in quality as compared with those in Experiments IV. and III. Leaving suspended solids out of account, the weak liquor effluent is distinctly better, relatively, than the effluent from the strong liquor. It will be noted, however, that even in this last experiment, after filtration through paper, only two of the thirteen strong liquor effluents failed on incubation, while all thirteen weak liquor effluents passed that test. The latter effluents might be described as fairly good, but the strong liquor effluents as rather poor. The spring outflush of solids again took place during this experiment, which—it must be borne in mind—was carried out for the most part in the coldest months of the year.

The work done on the filter treating strong liquor was 12,425 units and on the filter treating weak liquor 14,600 units.

It was evident, from the appearance of the filters during the progress of Experiment V., that they were being overtaxed, especially the strong liquor filter. The concrete at the base of the filters gradually became blackened and covered, more or less, with grey fungus, while at times the effluents smelt slightly of sewage.

187. Reviewing shortly the foregoing five experiments, we think that they may be taken to show that percolating filters of coarse material, 6 feet deep, can treat a strong septic tank liquor (strength 73 to 85) at a rate of 100 to 125 gallons per cube yard per day, or a liquor of half this strength at the rate of 200 to 250 gallons, giving from 8,000 to 9,000 units of purification, and producing at the same time a good effluent (apart from suspended solids).

Under favourable conditions of summer weather, a strong septic tank liquor (strength 74) can be treated at a rate up to 200 gallons per cube yard per day, or a liquor of half this strength at a rate up to 400 gallons per day, with from 14,000 to 15,000 units of purification and the production of a good effluent. This, we think, is probably the maximum work which can be expected from percolating filters of coarse material treating ordinary septic tank liquor at a regular rate of flow.

As regards the question whether it is easier to treat upon percolating filters of coarse material one volume of strong septic liquor or two volumes of weak, the organic impurity being the same in both cases, there is little difference either in the actual work done by the filters or in the quality of the effluents, at rates of working up to 200 and 400 gallons per cube yard per day. If any distinction is to be drawn, the advantage lies with the filter treating the weaker liquor, no doubt because the natural aeration of the extra volume of liquid rather more than counterbalances the quicker rate of flow through the filter.

Apart from complications arising from the presence of large quantities of suspended solids (*cf.* pp. 48 *et. seq.*), we think that the above statement with regard to the purification of strong and weak septic-tank liquors may be taken to apply also to settled sewage and precipitation liquor.

Double contact beds will, during their first year of work, at the rate of two fillings per day, treat 70 gallons of strong or 150 gallons of weak tank liquor per cube yard per day, with 5,000 to 6,000 units of purification for the first year. Their working power will, however, gradually fall off as the beds lose capacity. Here, again, it is rather easier to treat two volumes of weak than one volume of strong liquor.

It is clear from these experiments that, other things being equal, a greater purification per cube yard, as measured by the actual *amount* of oxygen used up, is effected when the final product is an *imperfectly* oxidized effluent. The indications are that, unit for unit, the first or carbon stage of the oxidation is, under the conditions of filtration, easier, or at least quicker, and therefore presumably requires less expenditure of energy than the second or nitrification stage. We may perhaps be able to make some further experiments with these filters, to clear up this point.

At the end of this section (*see* p. 121) we print in a summarized form tables of the results from a large number of places, most of which have been under our own observation.

General Conclusions as to the Working Power of Different Types of Filter.

188.—*Treatment of Crude or Partially Settled Sewage upon Double Contact Beds.*

The volume of sewage which can be treated by double contact, so as to give a fair or good effluent, varies almost inversely as the "strength," *e.g.*, 24 gallons per cube yard per day of sewage with a strength of 164, or 58 gallons of sewage with a strength of 60. During the "economic life" of the beds, an average of 3,000 to 4,000 units of purification per cube yard of filter per day may be looked for in the treatment of crude or settled sewage upon primary beds of coarse material and secondary beds of fine material, an effluent of fair to good quality being produced.

Treatment of Crude or Partially Settled Sewage on Percolating Filters.

Broadly speaking, the volume of sewage which can be treated upon percolating filters, with the production of a good effluent, depends mainly upon its strength, especially if no complications ensue through the choking of the filter and if the filter is working up to its full power. Twenty to 25 gallons per cube yard per day of a sewage having a strength of about 170, or 60 gallons of sewage with a strength of 60, can be successfully dealt with upon filters of medium to coarse material, 2,500 to 3,500 units of purification being obtained. When the sewage is *well settled*, about 100 to 120 gallons of such sewage with a strength of about 80, can be filtered per cube yard per day, and 7,000 to 8,000 units of purification, or probably even more than this,† obtained. In this case, therefore, the process is comparable with the treatment of septic liquor upon percolation filters.

Treatment of Septic Tank Liquor on Single Contact Beds.

The volume of septic tank liquor which can be treated by single contact varies almost inversely as the strength of the liquor. Single beds of medium to coarse or medium to fine material, may be expected to give from 3,000 to 4,500 units of purification, when dealing with either strong or weak liquors. If the tank liquor is a weak one, and if the material of the bed is fine, this purification will be sufficient to yield a good or fairly good effluent, but not otherwise. A weak liquor, of strength 30 to 50, and containing up to 6 or 8 parts of suspended solids, can in this way be successfully treated at the rate of 100 to 150 gallons per cube yard per day. As a rule, however, septic tank liquors are too strong to allow of one contact being sufficient to give a good effluent.

Treatment of Septic Tank Liquor on Double Contact Beds.

The volume of septic tank liquor which can be treated by double contact varies almost inversely as the strength. Where the *primary* beds are of medium to fine material a strong liquor of strength 90 may be treated by double contact at the rate of 50 gallons per cube yard per day; a liquor of strength 70 at the rate of 70 gallons; and a weak liquor of strength 40 at the rate of 100 gallons. From 3,500 to 4,500 units of purification may be expected here, with the production of good effluents.

Treatment of Septic Tank Liquor on Percolating Filters.

The volume of septic tank liquor which can be treated upon percolating filters varies more or less inversely as the strength. A percolating filter of coarse or of medium to coarse material, and from 6 to 9 feet in depth, may be expected to give from 7,000 to

† *Cf.* Appendix IV., Report to the Commission on the Dorking Experimental Installation, by E. H. Richards (1907).

11,000 units of purification when treating either strong or weak tank liquors, and to yield good effluents. This would correspond to 80 gallons per cube yard of a strong liquor of strength 113, or 150 gallons of a weak liquor of strength 58. The less coarse the material, provided that it can allow the free passage of effluent suspended solids through it, the greater is the relative purification per cube yard.

Treatment of Precipitation Liquor on Single Contact Beds.

Our data with regard to this process are rather few, but they indicate clearly that—as in the case of settled sewage and septic tank liquor—single contact of precipitation liquor from strong sewages is not sufficient to produce a good effluent. The better clarified the liquor, the more of it can be treated. The very well clarified liquor at Kingston-on-Thames, with a strength of about 50, was treated for over six years upon an experimental coke bed of medium to coarse material, 3 feet deep, at a rate of 250 gallons per cube yard per day (four fillings), giving 10,800 units of purification and producing a fair to good effluent. A more dilute tank liquor, equally well clarified, might be treated in even larger volume than this, so far as the " strength " was concerned, but it is doubtful whether more than four fillings per day would be practicable on a large scale for any length of time.

Treatment of Precipitation Liquor on Double Contact Beds.

We have had no actual experience of this process, which would be applicable to precipitation liquors from strong sewages. We should not expect, however, to obtain such a high figure for units of purification as in the treatment of medium or weak liquor by single contact. Probably about 6,000 to 7,000 units would be the maximum obtainable. This would correspond to about two to two and-a-half fillings per day of a liquor of strength 100 or about three to three and-a-half fillings of a liquor of strength 75.

Treatment of Precipitation Liquor on Percolating Filters.

In this case it cannot be said that the volume of precipitation liquor treated per cube yard of filter at the different places under observation varied inversely as the strength. The main reason for this is that suspended solids can be reduced in most precipitation liquors to a very low figure, in which case very fine material may be used for the filtration of large volumes. At the places which were under observation the filtering material varied greatly in size and the liquors contained very different quantities of suspended solids. Nevertheless with material of a given size, strength and volume would, no doubt, bear an inverse relation to one another. From the results obtained with percolating filters, of coarse and fine material, respectively, we have arrived at the following broad conclusions :—

(*a*) The volume of precipitation liquor which can be treated upon filters of *coarse* material depends mainly upon the strength of the liquor.

(*b*) The volume which can be treated upon filters of *fine* material depends not merely upon the strength, but also to a marked extent upon the degree of clarification of the liquor.

Upon deep filters of coarse material, about 150 gallons of precipitation liquor of about average strength (strength 50 to 60) or 200 to 250 gallons of weak liquor (strength 30 to 40) can be treated per cube yard per day, yielding up to about 8,000 units of purification, and producing a good effluent. In the case of very strong liquors the volume would probably have to be *more than* proportionately reduced.

Upon shallow filters of fine material a *clear* liquor with a strength of 50 can be treated at the rate of 300 to 400 gallons per cube yard per day, giving about 18,000 units of purification, and producing a very fair to good effluent. It has to be borne in mind, however, that filters of very fine material working at this rate have to be constantly washed and scraped. About 500 gallons per cube yard per day would probably be the largest volume of any liquor, however weak, that could be treated on such filters regularly, day by day.

The rates of treatment which are given in the foregoing paragraphs could generally be doubled in times of storm.

Summary.

189. The following tables gives an *approximate* idea of the purification which can be effected by different kinds of filter treating different liquors, so as to produce a fair to good effluent :—

	Units of Purification per cube yard :—
Crude or partially settled sewage treated on double contact beds	3,000 to 4,000
Crude or partially settled sewage treated on percolating filters	2,500 to 3,500
Well settled sewage treated on percolating filters	7,000 to 8,000, and probably up to 11,000
Septic tank liquor treated on single contact beds	3,000 to 4,500
Septic tank liquor treated on double contact beds	3,500 to 4,500
Septic tank liquor treated on percolating filters	7,000 to 11,000
Precipitation liquor treated on single contact beds	Up to 11,000
Precipitation liquor treated on double contact beds	*Probably* up to 6,000 to 7,000
Precipitation liquor treated on percolating filters :—	
(*a*) Filters of coarse material	Up to about 8,000
(*b*) Filters of fine material	Up to about 18,000

General Summary as to Contact Beds and Percolating Filters.

190. (1)—The amount of sewage which can be purified per cube yard of contact bed or percolating filter varies—within practical limits—nearly inversely as the strength of the liquor treated. This statement is based on the assumption that the size of the material of which the filter is composed is, in each case, suitable to the character of the liquor treated, and that the material is arranged at the proper depth to secure maximum efficiency (*see* Paragraph 153, p. 87).

(2) Taking into account the gradual loss of capacity of contact beds, a cubic yard of material arranged in the form of a percolating filter will generally treat satisfactorily nearly twice as much tank liquor as a cubic yard of material in a contact bed.

(3) In the case of sewage containing substances which have an inhibitory effect upon the activity of micro-organisms, the working power per cube yard of filter of either type may be more nearly equal. This point, however, is not clearly established.

(4) Percolating filters are better adapted to variations of flow than contact beds.

(5) The effluents from percolating filters are usually much better aerated than the effluents from contact beds, and apart from suspended solids, are of a more uniform character. On emptying a contact bed, the first flush is usually much more impure than the average effluent from the bed.

(6) The risk of nuisance from smell is greater with percolating filters than with contact beds.

(7) It is also found that with percolating filters, there is nuisance from flies, especially with filters constructed of coarse material. In the warmer months of the year, such filters swarm with members of the *Psychodidae*, which, though appearing to breed and develop in the filters, may usually be seen in large numbers on the walls of houses and buildings close to or on the works. At Accrington and Dorking a small midge-like fly with a dark body and striped wings has appeared and causes inconvenience to the men by its bite, which gives rise to local irritation.

TABLES OF ANALYTICAL RESULTS OBTAINED: (*a*) AT THE DIFFERENT SEWAGE WORKS WHICH HAVE BEEN UNDER OBSERVATION BY OUR OWN OFFICERS; (*b*) BY THE AUTHORITIES AT THE SEWAGE WORKS OF BIRMINGHAM, BURNLEY, HEYWOOD, HUDDERSFIELD, LEEDS, MANCHESTER, OLDHAM, AND SHEFFIELD.

Prefatory Note to Tables.

191. The figures of analysis given for crude and settled sewage, septic tank liquor, and precipitation liquor, refer to the *hourly* sets of samples only in the case of the works which have been under observation by our own officers, these hourly sets representing as far as possible the dry weather flow. For purposes of comparison, we have given the average figures for the *hourly* sets of effluent samples (*i.e.*, dry weather samples), and the average figures for the ordinary *chance* samples of effluent. There were, as a rule, a fair number of such chance effluents examined from each place, and the figures may generally be looked upon as representing roughly the average of the effluents obtained in all weathers. In the case of the other places (Leeds, Manchester, etc.) the figures given for the sewages, tank liquors, and effluents are the averages of a very large number of *chance* samples. These latter figures were furnished by the authorities of the various sewage works mentioned, and they are printed in italics to distinguish them from our own figures.

The figures for "oxygen absorbed in four hours" given in italics were obtained with weak permanganate, and therefore require to be multiplied by 1·6, in order to make them fairly comparable with our own *four hours*' figures, which were obtained with strong permanganate.

With regard to the bacteriological notes, wherever possible, the figures given refer to the number of B. Coli (or Coli-like microbes) per c.c. In the few cases where this test was not applied, or where the records were very few in number, approximate figures are given, based upon the results obtained by the use of one or more presumptive tests for B. Coli. The results frequently varied so much that the figures can only be taken as being roughly approximate; bacteriological results obtained by the decimal method of dilution do not lend themselves readily to expression in the form of averages. Further, a good deal of latitude has been exercised in the way of pitting high results against low results and ignoring exceptional ones. We think, therefore, that the bacteriological figures given in the following tables should be read in the light of the detailed tables which are incorporated in the text of the separate reports, printed in Appendix III.

TABLE I.—ANALYSES OF CRUDE SEWAGE.

No.	Place.	Population	System of Sewerage.	Dry weather flow of Sewage (gallons).	Nature of Sewage.	Analysis of Sewage. Parts per 100,000.				B. Coli per c.c.	Preliminary Grit Settlement.	Remarks.
						Ammoniacal Nitrogen.	Albuminoid Nitrogen.	Oxygen absorbed in 4 hours.	Suspended Solids.			
1	Hampton -	6,500	Separate	180,000	Strong domestic	9·40	1·38	17·82	48·5	At least 100,000.	Partial settlement on surface of primary beds.	
2	Leeds - -	450,000	Combined	15,500,000	Trade sewage	*3·28*	*1·26*	*14·10*	*85·0* D.	About 100,000.	Partial settlement	Experimental processes. Fixed quantity treated daily; compare D with Ducat filter effluent, C with contact bed effluent, and L with "Leeds" filter effluent.
						2·30	*0·65*	*10·27*	*53·3* L.			
						1·54	*0·85*	*10·80*	*52·5* C.			
3	Maidstone -	34,000	Partially separate.	1,500,000	Domestic, with much brewery and tannery waste.	3·51	1·52	21·03	34·8	At least 100,000.	Partial settlement in pump well.	Experimental process. Fixed quantity treated daily.
4	Newton -	9,000	Combined	145,000	Domestic (mainly slop water).	4.30*	0·86*	12·32	30·6	At least 100,000.	Slight settlement in distributing troughs.	
5	Withnell -	1,650	Partially separate.	15,000	Very strong domestic	5·35	1·23	21·19	33·9	At least 100,000.	Partial settlement in grit chamber.	Experimental process. Fixed quantity treated daily.

NOTE—The figures of analysis given in ordinary type are, as a rule, averages of three sets of twenty-four hourly samples, drawn in dry weather, according to rate of flow. The figures of analysis given in italics are, as a rule, averages of a large number of chance samples, drawn in all weathers. All figures for "Oxygen absorbed in four hours" given in italics, having been obtained with "weak" permanganate, must be multiplied by 1·6 to compare approximately with the figures for "Oxygen absorbed in four hours" given in ordinary type, the latter having been obtained with "strong" permanganate.

* These numbers are inferred; they will be nearly right.

TABLE II.—SETTLEMENT OF SEWAGE

No.	Place.	Population.	System of Sewerage.	Dry weather flow of Sewage (gallons).	Nature of Sewage.	Analysis of Sewage. Parts per 100,000. Ammoniacal Nitrogen.	Albuminoid Nitrogen.	Oxygen absorbed in 4 hours.	Suspended Solids.	B. Coli per c.c.
7	Clifton - -	2,000	Partially separate.	22,000	Strong slop-water domestic.	3·78	1·11	26·07	49·1	At least 100,000.
8	Halton - -	2,000	Combined	35,000	Domestic (mainly slop-water).	4·74	*0·85	11·83	17·7	At least 100,000.
9	Little Drayton -	1,550	Ditto	12,000	Strong slop water domestic.	7·57	1·41	24·44	23·9	At least 100,000.
10	Leeds - - -	450,000	Ditto	15,500,000	Trade sewage.	*1·92*	*0·68*	*11·34*	*58·1*	About 100,000.
11	Oswestry - -	9,800	Ditto	350,000	Domestic with brewery and tannery waste.	3·53	0·91	11·27	29·4	At least 100,000.
12	Sheffield - -	400,000	Ditto	14,500,000	Trade sewage.	*2·61*	*0·76*	*7·08*	*50·2*	
13	Oldham - -	—	Ditto	2,250,000	Rather weak domestic.	*3·17*	*0·77*	*5·60*	*51·2*	About 100,000.

NOTE.—The figures of analysis given in ordinary type are, as a rule, averages of three sets of twenty-four hourly a large number of chance samples drawn in all weathers. All figures for "oxygen absorbed in four hours" given with the figures for "oxygen absorbed in four hours" given in ordinary type, the latter having been obtained with

WITHOUT THE AID OF CHEMICALS.

Note. (*a*) The figures for oxygen absorbed in four hours given in italics, having been obtained with "weak permanganate," must be multiplied by 1·6 to compare approximately with the figures for "oxygen absorbed in four hours," given in ordinary type, the latter having been obtained with "strong" permanganate.

(*b*) The figures for albuminoid nitrogen in ordinary type may probably be rather too high in some of the above effluents.

* These figures are approximate. † This is an average of only two samples.

PART III.—PURIFICATION OF SEWAGE BY TREATMENT ON LAND.

Introductory Remarks.

192. There can be no doubt that, where the soil is suitable and the area of land sufficient, the organic matters in sewage can be thoroughly oxidised by land treatment.

This fact is well established, not only by investigations made by earlier Commissions, but also by wide general experience.

The investigations of earlier Commissions did not, however, extend to the bacteriological side of the question, and for this reason, and in order to compare the treatment of sewage on land with its treatment by other methods, we considered it necessary to examine the working of some sewage farms.

Prior to commencing our investigations, a large number of sewage farms were visited, and we ultimately selected, for systematic observation, the following farms :—

Aldershot Camp	Sand.
Croydon (Beddington)	Gravelly loam.
Nottingham	Light loam.
Cambridge	„ „
South Norwood	Heavy loam and clay.
Leicester	„ „ „ „
Altrincham	Peaty soil and sand.
Rugby (high level farm)	Heavy loam.

Some few samples of effluent were also taken from, and some observations made at, Luton (chalk), Worsley (peat and gravel), Hemsworth (clayey soil), Derby County Asylum (stiff soil overlying red clay), Lindfield (clayey soil), Sandhurst (sandy soil), and Woking (Bagshot sand).

Our investigations extended over a period of more than two years, and detailed particulars in regard to them are contained in the Reports made to us by our officers, which were published as supplementary volumes to our Fourth Report.

Comparison of Effluents from Land and from Artificial Filters.

193. Judged by chemical analysis, both classes of effluent possess similar qualities.

As regards the eight farms which we have had under observation, the average purification, calculated on the atmospheric oxygen used up, and giving credit for the oxygen contained in the effluent in the form of nitrate, was about 98 per cent. It would have been rather higher than this if the suspended solids had been eliminated from those effluents which contained them.

As regards seven contact bed plants, which we have examined, the average purification on the same basis, but eliminating the suspended solids, was 93·4 per cent.

As regards six installations of percolating filters, our analyses show that the average purification, after eliminating the suspended solids, was 99·4 per cent.

The following tables, A and B, give the average figures of the chemical analyses of the sewage and effluents at the eight farms; Table C gives certain percentages for each farm.

Table A—Table of Average Figures showing the Chemical

These Tables show that the strength of the several sewages varied somewhat widely, that the average quality of the effluents from the several farms also varied, and further, that the effluents from the same farm were by no means of uniform quality.

Nottingham was the only farm from which none of the effluents which were examined putrefied upon incubation, and in this case the amount of sewage treated was only 10,750 gallons per acre per day, and very little storm water was treated.

Speaking generally, the effluents which we have examined from artificial filters, as at present constructed and used, are not equal in purity to effluents from the best land, when treating a comparatively small quantity per acre, as at Nottingham ; but effluents from heavy land are often of very inferior quality. Moreover, in the case of some kinds of land, we think that the danger of some of the sewage escaping in an unpurified condition is greater than it is in the case of artificial filters, assuming equally careful management in the two cases.

Bacteriological Character of Effluents.

194. Our investigations have not shown that there is any essential bacteriological distinction between effluents from land and effluents from artificial filters, though effluents from land usually contain fewer micro-organisms than effluents from the artificial filters which are at present in use. The bacteria in the filter effluents can, however, be largely reduced, if this is necessary, by some additional process, such as sand filtration or sterilization,* but for the reasons which are given under the section of this Report dealing with standards, we do not consider that the further process would usually be required.

There is, no doubt, a greater retardation in the passage of an excremental organism through soil than through artificial filters, at the rates of working generally followed in the two cases : this is probably a factor of importance in relation to the life and virulence of certain pathogenic microbes.

The following table gives the average figures for the bacteriological analysis of the final effluents from the eight sewage farms, the figures in brackets shewing the percentage reduction in each case upon the original sewage treated.

	Altrincham.	Aldershot Camp.	Croydon (Beddington).	Cambridge.	Leicester.	Nottingham ‡.	Rugby.	South Norwood.

* *See* Dr. Houston's Report on Sterilization, Appendix IV.

(†) These averages are only approximate.

(‡) The effluents from the Nottingham farm stand in a class by themselves. Some of them were so pure bacteriologically as to resemble drinking water, but still the figures were variable. (For details, cf. Bacteriological Report to the Commission by Dr. A. C. Houston, Fourth Report, Vol. IV., Part III.)

From a bacteriological point of view, the treatment of sewage on land, may, under favourable conditions, reduce the bacteria to quite a remarkable extent. This is shown in the foregoing Table, the reduction both in the total number of bacteria and in the bacteria growing at 37° C. (blood heat) varying from 94 per cent. to 99 per cent. But, notwithstanding this large percentage reduction, it will be seen from Dr. Houston's detailed Report* that the number of microbes of undesirable sort remaining in the effluent may often be very great.

Volume of Sewage which can be Treated on Land.

195. The witnesses whom we examined on the question of the land treatment of sewage were not unanimous as to the basis on which the extent of land required should be calculated. Mr. F. Scudder and Mr. Santo Crimp considered that the basis should be the volume of sewage to be dealt with, but Mr. Baldwin Latham expressed the view that the area of land must be determined by the population draining to the farm, as indicating the strength of the sewage. The quality of the land itself must, of course, always be taken into account. Another factor to which importance was attached was the nature and extent of the preliminary treatment, if any, that the sewage receives before it is put on the land.

Scudder, 570. Santo Crimp, 1573. 4662-4. 4515-16.

Generally speaking, the evidence points to a maximum rate of 30,000 gallons per acre, or 1,000 persons per acre, with the best land, after preliminary treatment, although some witnesses put the rate as high as 60,000 gallons per acre, or 2,000 persons per acre, under similar conditions. With unsuitable land, such as clay, not more than 3,000 gallons per acre can be efficiently treated, even after settlement of the sewage.

Santo Crimp, 1571-2. Strachan, 7629-30. Roscoe, 3741 & 3744. Balfour, 6859-63.

Mr. R. A. Tatton handed in the following Table showing the approximate areas required with different soils :—

Tatton, 6578. 6578.

	Direct to Land.		After Precipitation or Mechanical Settlement.		After Filtration on Bacteria Beds.	
	Ratio of Population per Acre.	Acres per 1,000 Persons.	Ratio of Population per Acre.	Acres per 1,000 Persons.	Ratio of Population per Acre.	Acres per 1,000 Persons.

196. With regard to the eight sewage farms which we had under our own observation, we give in the appended Table a statement of the nature and extent of the land, the volume dealt with, and a brief summary of our conclusions.

* *See* Vol. IV., part III., presented with our Fourth Report.

Name of Farm.	Nature of Sewage.	Nature of Soil and Subsoil.	Method of Treatment.	Area of Land under Treatment.	Volume treated per acre of land under treatment per 24 hours.	Population per acre of land under treatment.	Observations.
				Acres.	Gallons.		
Aldershot Camp	Domestic	Sand.	Screening, settling tanks and land filtration.	120½	8,300	166	The volume treated per acre was rather too large to yield effluents of the highest class, though the effluents showed a high percentage of purification. The sewage is exceptionally strong at Aldershot.
Altrincham	Domestic	Peaty soil, lying upon sand and gravel.	Settling tank and land filtration.	35	23,000	514	With a somewhat smaller volume of sewage per acre, probably the results would be distinctly good.
Cambridge	Mainly domestic	Sandy loam overlying gravel and sand.	Screening and settling tank and land filtration.	74	30,400	675	The effluents were usually good, but 30,400 gallons per acre was rather too large a volume to yield effluents of the highest class.
Croydon (Beddington) ...	Domestic	Gravelly loam over gravel and sand.	Screening and partly surface irrigation partly filtration.	420	9,500	238	With the method of treatment adopted 9,500 gallons per acre was too large a volume to yield an effluent of the highest class. If the 420 acres of land were laid out solely for filtration, no doubt a larger quantity of sewage could be treated per acre.
Leicester	¾ domestic; ¼ trade refuse	Stiff clayey soil overlying dense clay.	Screening, settling tanks, and surface irrigation and filtration combined.	1,350	5,370	146	The land was treating rather too large a volume per acre to yield effluents of the highest class.
South Norwood	Domestic	Clay soil resting on London clay.	Screening, settling tanks and surface irrigation.	152	4,000	138	The results indicated that rather too large a volume of sewage was put on the land to yield effluents of the highest class.
Nottingham	4/7 domestic, 3/7 trade refuse	Light sandy loam and gravel overlying gravel and sand.	Screening and land filtration.	651	10,750	397	The effluents were uniformly of exceptionally high quality, as judged by chemical analysis.
Rugby	Mainly domestic	Heavy loam overlying stiff clay.	Screening, chemical precipitation, settling tanks, and surface irrigation and filtration combined.	35	8,500	171	The volume treated on the land per acre was too large to yield effluents of the highest class.

197. It will be seen that, at Nottingham, where the soil is well adapted for the purification of sewage, the volume of sewage treated per acre was only 10,750 gallons. The results were exceptionally good, and there is little doubt that a larger volume could have been efficiently purified. At Cambridge, which has the same kind of soil and subsoil, the volume treated per acre, viz., 30,400 gallons, proved rather too large to yield an effluent of the highest class. Taking the two places together, the results may perhaps be regarded as supporting the evidence of witnesses that sewage can be treated at the rate of 30,000 gallons per acre per day on the best soils.

In other cases, where the soil is of a heavy nature and not so well adapted for the purification of sewage, the results again seem to corroborate the views of witnesses as to the volume which can be dealt with on unsuitable soils, viz., not more than 3,000 gallons per acre per 24 hours, if a good effluent has to be produced.

The total acreage of a farm must be relatively much greater when the sewage is purified by surface irrigation than when the method of filtration is employed, and a larger percentage surplus area is also desirable in the former case. We are not able to lay down any rule as to what the ratio of surplus acreage to total acreage should be, but generally speaking, a large surplus area is advisable.

It is true that the larger the total irrigable area, the greater is likely to be the working cost. On the other hand, with good management, the larger the surplus irrigable area, the better is the purification likely to be and—within certain limits—the prospect of profit.

198. The following Tables D, E, F, have been compiled, with a view to showing in some detail, the amount of purification work which was done, per unit area, at the farms which we had under observation.

The figures for strength of sewage, strength of effluent, and units of purification are arrived at on the bases already explained.

TABLE D.

Name of Farm.	Population per acre of land under treatment.	Relative figures of population per acre of land under treatment.	Gallons of sewage treated per acre of land under treatment, per day.	Gallons of sewage treated per square yard of land under treatment, per day.	Relative figures.	Relative oxidizable matter treated per square yard (*i.e.*, gallons per square yard "strength" figure for sewage).	Relative figures.	Ratio of oxidizable matter treated per unit area to volume treated per unit area.	Gallons of sewage per head per day.
Cambridge - - - -	675	100	30,400	6·28	100	666	100	1 : 9·4	45
Altrincham - - - -	514	76	23,000	4·75	76	259 (?)	39 (?)	—	44
Nottingham - - - -	397	59	10,750	2·22	35	404	61	1 : 5·5	27
Beddington - - - -	238	35	9,500	1·96	30	218	33	1 : 9·0	40
Rugby - - - - -	171	25	8,500	1·76	28	296	46	1 : 5·8	50
Aldershot Camp - - -	166	25	8,300	1·72	27	332	50	1 : 5·2	50
Leicester - - - - -	146	22	5,370	1·11	18	180	28	1 : 5·9	37
South Norwood - - - -	138	20	4,000	0·83	13	61	9	1 : 13·7	29

TABLE E.

Name of Farm.	Gallons of sewage treated per square yard of land under treatment per day.	"Strength" of Sewage.	"Strength" or oxidizability of effluent (including the nitrate).	Parts by weight of oxygen used in oxidizing 100,000 parts of sewage (including the oxygen required to produce the nitrate of the effluent).	"Units of purification" effected per square yard.	Average depth to drains.	"Units of purification" effected per cube yard.	Percentage purification calculated on "Oxygen absorbed" in 4 hours from permanganate (chance effluents compared with hourly sewages).
Cambridge - - - - - -	6·28	106 (2)	0·0	106	666	4 ft. 6 in.	381	92 per cent.
Altrincham - - - - - -	4·75	54·5 ? (1)	4·4	50·1	238	3 ft. 9 in.	190	?
Nottingham - - - - - -	2·22	182	— 5·0	187	415	7 ft. 0 in.	178	99
Beddington - - - - - -	1·96	111	6·7	104·3	204	2 ft. 3 in.	272	89
Rugby - - - - - -	1·76	168	7·4	160·6	283	Say 2 ft. 0 in.		92
Aldershot Camp - - - - -	1·72	193	1·0	192	330	3 ft. 3 in.	305	87
Leicester - - - - - -	1·11	168 (2)	8·0	160	178			88
South Norwood - - - - -	0·83	73	3·6	69·4	57·6			81

(1.) ALTRINCHAM.—In this case the "strength" is calculated from 4 *chance* samples of sewage plus 5 *chance* samples of lagoon liquor. The figure for "strength" is therefore not nearly reliable as in the other cases; probably it is considerably below the truth.

(2.) Making correction for abnormal ratio between "oxygen absorbed" from permanganate *at once* and *in* 4 *hours* in the cases of Cambridge and Leicester.

TABLE F.

Name of Farm.	(*a*) Sewage treated.	(*b*) Gallons per acre of land under treatment, per 24 hours ÷ 1,000	(*c*) Calculated strength of sewage.	(*d*) Relative oxidizable matter treated on unit area (b × c).	(*e*) Population per acre of land under treatment.	(*f*) Relative oxidizable matter treated per head of population (d ÷ e).
Cambridge - - -	Screened and settled.	30·4	106	3,222	675	4·8
Altrincham - -	Very well settled in lagoons.	23·0				
Nottingham - -	Screened and crude.	10·8	182	1,966	397	5·0
Beddington - -	Screened and settled.	9·5	111	1,055	238	4·4
Rugby - - -	Screened and settled.	8·8	168	1,478	171	8·6
Aldershot Camp - -	Screened and settled.	8·3	193	1,602	166	9·0
Leicester - - -	Screened and settled.	5·7	168	908	146	6·2
South Norwood - -	Screened and settled.	4·0	73	292	191	1·5

The figures in column (*f*) for relative oxidizable matter per head shew marked divergences, but still, if we except South Norwood, where the figure is probably below the truth, the extreme limits are only 4·4 and 9 or 1 : 2. The highest figures occur at Aldershot Camp and Rugby, where the sewages (domestic) are very strong.

199. The following points are brought out by these Tables :—

The *relative* figures for population per acre irrigated, and for gallons per day, follow one another pretty closely, excepting in the case of Nottingham.

The *relative* oxidizable matter per head of population varied from about 1 to 2. It was greatest in the stronger sewages.

The *relative* "strength" of the sewage per gallon, *i.e.*, oxidizable matter per gallon, varied roughly from 1 to $2\frac{1}{2}$, but it was nearly constant for the less strong sewages.

The volumes of sewage (screened and settled in nearly every case) treated per 24 hours at the different farms ranged between 0·83 and 6·28 gallons per square yard, or between 4,000 and 30,400 gallons per acre.

200. The quantity of sewage which can be treated upon an unit area of land is necessarily small, because of the fineness of the filtering medium. Apart from this it is dependent upon a number of factors, of which the principal are :—

(*a*) Whether surface irrigation or filtration is followed.

(*b*) The quality and depth of the soil and subsoil.

(*c*) Whether or not the land is cropped.
(*d*) The strength of the sewage or sewage liquor.
(*e*) The degree of clarification of the liquor.

We have had no opportunity of ascertaining, quantitatively, whether it is easier with land treatment to purify one volume of strong sewage, or two volumes of a sewage of half the strength. We should infer, however, that the results with land would be so far analogous to those with artificial filters that, within ordinary limits of strength of sewage, *and so long as water-logging of the land was avoided*, there would be no appreciable difference in purification in the two cases. Since, however, a fine filtering medium like soil readily tends to become clogged on the surface, and, therefore, becomes sodden sooner than the relatively coarse medium of artificial filters, we think it would generally be found easier to treat upon land one volume of a strong sewage rather than two volumes of a sewage of half the strength, and that, therefore, with land treatment, the volume of liquid to be dealt with is of greater consequence than its actual strength.

Physical Texture of Soils.

201. A detailed account of the mechanical analyses of the soils and subsoils of the principal farms under observation is to be found in Volume IV., Part II., presented with our Fourth Report.* The results of these mechanical analyses, while too few to allow of general deductions being drawn, show that it is possible to say from the mechanical analysis of a soil whether or not it would be suitable for purifying sewage by filtration, and the same statement holds true, though in a lesser degree, as regards suitability for surface irrigation.

Preliminary Settlement of Sewage before Land Treatment.

202. In the case of sewage which is to be treated upon artificial filters, it is generally desirable to settle out as much of the suspended solids of the sewage as possible before filtration. This is of less moment in the case of land, but where the soil is heavy we think that the sewage should usually be efficiently screened and settled. Porous sandy soils, worked as filtration farms, may be able to treat crude unsettled domestic sewage without detriment, but, even in those cases, there is the possibility of nuisance arising from the decomposition of sewage solids on the surface of the soil, and such solids may cause damage to crops.

Disposal of Sludge at Sewage Farms.

203. At a sewage farm the disposal of the sludge offers no particular difficulty, the land treatment of sewage possessing in this respect a great natural advantage over artificial treatment.

The question of the disposal of sludge generally is dealt with in a later section.

Evaporation and Absorption of the Water of Sewage in Land Treatment.

204. In the artificial filtration of sewage or sewage liquor, practically all the sewage which flows on to the filter appears as effluent, very little evaporation taking place. In the case of land purification, however, especially where crops are grown, the liquid is partly absorbed by the plant and partly evaporated, and consequently, the volume of the resulting effluent is materially less than that of the original sewage. Indeed, in warm weather, very little effluent passes away from surface irrigation farms treating moderate volumes of sewage.

Loss of Nitrogen from Sewage during its Purification.

205. The most important manurial constituent of sewage is the ammonia which is produced by the fermentation of the urea of the urine, but it also contains organic nitrogen

* Mechanical Analysis of Soils and Subsoils. By G. McGowan and R. S. Finlow.

compounds in smaller quantity, together with phosphates and salts of potash. In the process of sewage purification by artificial filtration, varying quantities of the nitrogen of the ammonia and other compounds disappear, partly, no doubt, from conversion into gaseous nitrogen, and partly from being assimilated by vegetable growths, worms, flies, etc.; the remainder of the nitrogen is converted (in a well purified effluent) into nitrate. The following average figures, obtained from our own work, may be taken as giving a fair idea of the amounts of nitrogen which disappear during the treatment of sewage and sewage liquors upon contact beds and percolating filters, and upon land. In the latter case, much of the nitrogen which has vanished has been used up by growing crops.

	Percentage of the Nitrogen of Sewage or Sewage Liquor which disappears during the Process of Purification.
Land Surface Irrigation of Sewage - - - - -	About 60 (40 to 75).
Land Filtration of Sewage - - - - - -	
Treatment of Sewage on Percolating Filters - - -	40 to 50.
„ Septic Liquor on Contact Beds - - -	40 to 45 Single Contact. 40 to 50 Double Contact.
„ Septic Liquor on Percolating Filters - -	30 to 40 or less.
„ Precipitation Liquor on Contact Beds - -	25 (Single Contact.)*
„ Precipitation Liquor on Percolating Filters -	40 to 50.

206. It is in the form of nitrate that nitrogen is taken up by most plants. Much has been written about the loss to the country arising from the non-utilisation of the nitrogen of sewage which has been purified by artificial filtration, a loss which is certainly to be deplored. It is, however, frequently forgotten that when water-borne sewage is purified on land, upon which grass or other crops are grown, loss of nitrogen is, to a large extent, unavoidable in the colder seasons of the year, since plants can only assimilate nitrate very slowly in cold weather. As regards the production of nitrate in the soil, it is well known that this is largely influenced by temperature, coming practically to a standstill when the temperature is very low, but it is probable, we think, that in this country the temperature would very rarely be sufficiently low for a long period, to arrest nitrification. During our observations on sewage farms, we had no experience of a very severe winter, but nitrification was not materially hindered by such cold as we did experience. It will, of course, be remembered, in this connection, that the temperature of sewage itself is comparatively high.

In Vol. IV., Part IV., of the Report to the Commission upon Land Treatment (Engineering and Practical), by Mr. Kershaw, are diagrams giving the daily temperatures, over a year, of air, sewage, and effluent at the sewage farms of Nottingham, Aldershot Camp, South Norwood, and Beddington. On only one occasion during the winter of 1900–1 did the temperature of the sewage at Nottingham fall below 50° F., while the lowest temperatures for sewage at other farms were 46° F. at Beddington, 42° F. at South Norwood, and 40° F. at Aldershot Camp. The diagrams also show the equalising effect, as regards temperature of effluent, of the filtration farms, Aldershot Camp and Nottingham, while in the case of the surface irrigation farms of Beddington and South Norwood, the temperature of the effluent follows that of the air pretty closely.

There is, unfortunately, no economical method of extracting the nitrate from a sewage effluent otherwise than through the agency of plants, and, as we have stated, there must of necessity be a considerable loss of valuable nitrogenous manure from water-borne sewage, even in the case of land purification. In the case of artificial filtration, supposing

* This figure is from one installation only.

the effluent to be subsequently discharged into a stream, the loss is, of course, much greater, all the manurial constituents of the sewage, apart from those in the sludge, being wasted. They will, it is true, augment the vegetable growths in the stream itself, but this is nearly always more or less objectionable.

Is a Sewage Farm Dangerous to Health?

207. No proof has yet been furnished of direct or wide-spread injury to health, in the case of well-managed sewage farms. It is interesting to note here that the Report for 1905 on the sewage farm of Berlin contains the following statement :—

"We can only repeat here what we have said in previous Reports—that the sewage treatment (*Rieselbetrieb*) has had no injurious effect upon health."

This farm covers an area of nearly 39,000 acres of sandy soil, and there was on the ground in 1905 a resident population of 4,198 persons.

Wells in the Neighbourhood of Sewage Farms.

208. We have examined too few samples of well water in the neighbourhood of sewage farms to allow of our drawing any safe conclusions, on experimental grounds, as to the admissibility of such wells. But on general grounds, and quite apart from any scientific data, it would seem to be unsafe to sink any shallow wells in the neighbourhood of sewage farms, or to use water for domestic purposes from any such existing wells, unless the evidence as to the safety of the water were of a most convincing kind.

Deep wells sunk through an impermeable stratum are probably safe in the majority of instances, but wells not protected in this way, and sunk through fissured strata, can not be relied on to yield a safe water supply, however deep they may be.

Chalk wells are, perhaps, the most dangerous in this respect, and a recent Report by Dr. Copeman on an outbreak of enteric fever at Fulbourn Asylum,* and a paper † read at a recent meeting of the Epidemiological Society by Drs. Richards and Brinker, serve to confirm this view in a striking manner. The latter mention that a culture of a special organism was poured into a "swallow" hole at a distance of about two miles from the well, and was recovered from the well water after 67½ hours. It is doubtful whether sewage farms on chalk should be permitted without wide knowledge of the trend of underground water in relation to water supplies.

An attempt was made to collect an effluent on the Luton farm by digging a pit in the chalk, and in this way a few samples were obtained. The results, so far as they went, showed that *apart from the purification effected by the surface soil*, sewage underwent comparatively little purification in its passage through about three feet of chalk.

Sewage Farms on Peat Land.

209. Peat being of the nature of a sponge is not suitable for sewage purification, because of the difficulty of draining it, and the consequent lack of aeration. Some observations were made at the Worsley Sewage Farm, part of which is on peat land, and the results obtained there bear out this statement. The details of these observations are to be found in Vol. IV., Parts I. to IV., presented with our Fourth Report.

Management of Sewage Farms.

210. It is impossible to lay too much stress on the importance of sewage farms being well managed. In this connection it has to be borne in mind that farm managers have a most difficult part to play, and no amount of care and attention will ever enable land, of any kind, to deal with a volume of sewage which is in excess of the effective purifying area of the soil. We think it would be useful that farm managers should be taught some simple test or tests to enable them to follow the operations of the land; that their instructions should include a definite order to consider the farming results as quite secondary to the production of an effluent of the required standard; that the statistics of the farm should be carefully kept; and that, wherever possible, the flow of sewage and storm water should be gauged throughout the year.

As a general rule, we consider that sewage farms should not be let.

† The Potential Danger of Water derived from Wells in the Chalk.

Some Observations as to the Cost of Land Treatment of Sewage.

211. The cost of land treatment, as in the case of artificial filtration, varies with local conditions, and no figures can be given which would be generally applicable. In Table I. we give the annual cost per 1,000,000 gallons and per head for the eight sewage farms which we had under our own observation for over two years. In each case, the cost per 1,000,000 gallons is based upon the dry weather flow of sewage. The actual flow, however, included large volumes of storm water in most cases.

Table I.

Farms which were under continuous observation by officers of the Commission for over two years.

Place.	Population draining to farm.	Dry weather flow of sewage in gallons per 24 hours.	Net cost of treating the sewage per million gallons (including loan charges), based on the dry weather flow.	Net annual cost of treatment per head of population draining to farm, including loan charges.
		Gallons.	£ s. d.	s. d.
South Norwood -	21,000	600,000	*15 9 7	*3 $2\frac{1}{2}$
Leicester - - -	197,000	7,250,000	5 12 $8\frac{1}{2}$	1 6
Croydon (Beddington)	100,000	4,000,000	5 7 $5\frac{3}{4}$	1 $6\frac{3}{4}$
Cambridge - -	50,000	2,250,000	2 5 $5\frac{3}{4}$	0 9
Aldershot Camp -	20,000	1,000,000	†1 18 4	†0 $8\frac{1}{4}$
Rugby (High Level)	6,000	300,000	1 9 $8\frac{1}{2}$	0 $6\frac{1}{4}$
Altrincham - -	18,000	800,000	1 3 $3\frac{3}{4}$	0 $4\frac{1}{4}$
Nottingham - -	258,000	7,000,000	The figures of cost cannot be given for Nottingham. Excluding loan charges, cost of pumping, and rent of farm, however, there is usually a small profit on the year's working of the farm, which covers the cost of labour and also part of the rent.	

212. With a view to making some comparison between the cost of land treatment and the cost of treatment by "artificial" processes, we have thought it useful to work out the cost of treating on land a dry weather flow of 1,000,000 gallons a day, in certain hypothetical cases, following the plan adopted in regard to filters.

It is assumed for the purpose of this comparison :—

That, in the case of surface irrigation, sufficient fall is available, and that, in the case of filtration, the land is fairly level, admitting of its being used without abnormal expenditure in levelling and grading.

That the sewage to be treated is of a normal domestic character and of average strength (*i.e.*, gives a *four hours* "oxygen absorbed" figure of 10 to 12 with strong permanganate, and requires about 100 parts by weight of oxygen for the complete oxidation of 100,000 parts).

That the flow of sewage is one million gallons per day in dry weather.

That the district is sewered on the combined or the partially separate system.

That the cost of the land is £100 per acre.

*These figures include cost of pumping the effluent from the lower to the higher portions of the farm.

† No loan charges in the case of Aldershot Camp.

The soils and subsoils which we have considered, may be divided into the following three broad classes :—

Class I. All kinds of good soil and subsoil, *e.g.*, sandy loam overlying gravel and sand as at Nottingham, Cambridge, and Beddington.

Class II. Heavy soil overlying clay subsoil, as at Rugby.

Class III. Stiff clayey soil overlying dense clay, as at Leicester and South Norwood.

Since variations exist in practice, both as regards the method of purification employed and the extent of cropping, the first of these three classes may be divided into three sub-classes, as follows :—

Class I.
- Sub-class a. Filtration with cropping.
- Sub-class b. Filtration with little cropping.
- Sub-class c. Surface Irrigation with cropping.

The method of purification assumed for the other classes of soil are :—

Class II. Surface Irrigation with cropping.

Class III. Surface Irrigation with cropping. With a heavy soil and clay subsoil, by far the greater part of the purification is effected by surface irrigation, though in exceptional circumstances, such as obtain at Leicester, a good deal is also done by filtration.

213. Having regard to the volume of sewage dealt with and the purification effected at the farms which were kept under our own observation, and the evidence given by various witnesses, we estimate that the several classes of soil and subsoil could effectively deal with the volumes of settled sewage given in Table II.

TABLE II.

Class of soil and subsoil, and method of working.	Volume of settled sewage which can be dealt with per acre per 24 hours.	Total area of land required to deal with a dry weather flow of one million gallons.*
Class I. Sub-class a. Filtration with cropping	12,000 gallons	84 acres
Class I. Sub-class b. Filtration with little cropping	25,000 gallons	40 acres
Class I. Sub-class c. Surface irrigation with cropping	7,000 gallons	145 acres
Class II. Surface irrigation with cropping	5,000 gallons	200 acres
Class III. Surface irrigation with cropping	3,000 gallons	334 acres

* These areas are sufficient for the treatment in times of storm water of three times the mean dry weather flow.

Preliminary Tank Treatment.

214. At many of the sewage farms named in Table I. there is no preliminary settlement of the sewage, while at some of them the preliminary process does not secure anything like complete removal of the suspended matter.

For the purpose of our comparison, however, we have assumed preliminary settlement of the sewage in tanks of the capacities indicated in Table III:—

TABLE III.

Class of soil and subsoil and method of working.	Average stay in tanks.	Total number of tanks.	Number of spare tanks.	Total capacity of tanks (gallons)	Constructional cost of tanks.*
Class I. Sub-class a. Filtration with cropping	4½ hours	4	1	250,000	£2,230
Class I. Sub-class b. Filtration with little cropping	4½ hours	4	1	250,000	£2,230
Class I. Sub-class c. Surface irrigation with cropping	4½ hours	4	1	250,000	£2,230
Class II. Surface irrigation with cropping	15 hours	8	2	833,333	£5,112
Class III. Surface irrigation with cropping	15 hours	8	2	833,333	£5,112

* The estimates of the constructional cost of tanks are strictly comparable with the estimates for similar plant in connection with the artificial processes, and have been obtained by preparing drawings and taking out quantities.

Cost of Preliminary Tank Treatment and Disposal of Sludge.

215. We estimate that the working of the tanks and the disposal of the sludge, including trenching the land and covering the sludge, would require the services of two men for each of the first three classes (4½ hours sedimentation), and the services of three men for the other two (15 hours sedimentation).

Taking labourers' time at 21s. per week, and including one-third of the manager's time at a salary of £130 per annum, the following figures are obtained:—

TABLE IV.

Class of soil and subsoil and method of working.	Labour and supervision in connection with tanks and disposal of sludge.	
	Per annum.	Per million gallons of sewage (dry weather flow).
	£	s. d.
Class I. Sub-class a. Filtration with cropping	152	8 4
Class I. Sub-class b. Filtration with little cropping	152	8 4
Class I. Sub-class c. Surface irrigation with cropping	152	8 4
Class II. Surface irrigation with cropping	208	11 5
Class III. Surface irrigation with cropping	208	11 5

In the case of Classes II. and III. (heavy soils and subsoils), it would generally be advisable to eliminate the suspended solids from the sewage to a greater extent than in the other class where the soil and subsoil are of good quality.

With an average domestic sewage, the suspended solids after 4½ hours settlement (continuous flow) would be about 20 to 25 parts per 100,000, and, after a 15 hours settlement (continuous flow), from 10 to 15 parts per 100,000.

Converting these amounts of suspended solids into tons of wet sludge per million gallons, the quantities of sludge to be disposed of are approximately as follows :—

TABLE V.

Class of soil and subsoil and method of working.	Wet sludge (90% water) produced per million gallons from the average daily flow.	Area of land estimated to be required for disposal of the sludge.
Class I. Sub-class a. Filtration with cropping	8 to 10 tons	5 acres
Class I. Sub-class b. Filtration with little cropping	8 to 10 tons	5 acres
Class I. Sub-class c. Surface irrigation with cropping	8 to 10 tons	5 acres
Class II. Surface irrigation with cropping	17 to 20 tons	12 acres
Class III. Surface irrigation with cropping	17 to 20 tons	20 acres

Table VI. shows the total areas of land required for treatment of the sewage and for disposal of the sludge, and the total cost of land and tanks.

TABLE VI.

Class of soil and subsoil.	Total area of land required to treat a dry weather flow of one million gallons.	Area of land required for disposal of sludge.	Total area.	Total cost of land at £100 per acre.	Cost of laying out land, including levelling, grading, underdrains, carriers, etc.	Cost of tanks.	Total cost.
				£	£	£	£
Class I. Sub-class a	84 acres	5 acres	89 acres	8,900	6,334	2,230	17,464
Class I. Sub-class b	40 acres	5 acres	45 acres	4,500	4,589	2,230	11,319
Class I. Sub-class c	145 acres	5 acres	150 acres	15,000	4,494	2,230	21,724
Class II.	200 acres	12 acres	212 acres	21,000	5,770	5,112	32,082
Class III.	334 acres	20 acres	354 acres	35,400	7,599	5,112	48,111

216. With regard to the underdraining of land, the necessity for drains depends not merely upon the nature of the soil and subsoil, but upon the volume of liquid dealt with per acre. A porous soil and subsoil like that at Beddington can be made to answer perfectly well without underdrains, when a moderate volume of sewage is applied; when, however, a large volume is applied, underdrains are necessary, in order to assist the land to "dry-off" sufficiently rapidly.

In Sub-class a (Class I.), we have assumed that the tributary drains average 6 feet in depth and are laid 66 feet apart.

In Sub-class b (Class I.), where the volume of liquid applied is larger, and the area proportionately less, the tributary drains, also 6 feet deep, have been placed 50 feet apart.

In the case of the surface irrigation farms (Sub-class c and Classes II. and III.), underdrainage has been allowed for, to provide for the contingency of possible over sewaging of the plots; but in the case of the heavy soils and subsoils we have assumed that the drains are only laid at a depth of 2 feet 6 inches and that they are brought to the surface of the ground to admit of re-treatment of the effluent by surface irrigation.

Loan Charges.

217. Table VII. gives the loan charges in respect of cost of land, tanks, etc., on the basis of loans raised for thirty years, at 3½ per cent. interest per annum.

TABLE VII.

Class of soil and subsoil and method of working.	Loan charges in respect of land, tanks, laying out land, underdrains, etc.	
	Per annum.	Per million gallons of sewage. (dry weather flow).
	£ s. d.	£ s. d.
Class I. Sub class a. Filtration with cropping	949 12 1	2 12 0
Class I. Sub-class b. Filtration with little cropping	615 9 5	1 13 8¾
Class I. Sub-class c. Surface irrigation with cropping	1,181 4 10	3 4 8¾
Class II. Surface irrigation with cropping	1,744 9 2	4 15 7
Class III. Surface irrigation with cropping	2,616 0 8	7 3 4

Labour in connection with the Distribution of the Sewage.

218. The number of men required in connection with the distribution of the sewage, etc., must of course depend largely upon the nature and contour of the lands sewaged, and upon the nature of the crops raised, whether stock is kept, etc.

From numerous examples of land treatment, however, we find that roughly speaking one man can attend to the distribution of the sewage over about 40 acres.

It has been assumed in the present comparison that the services of the men who undertake the sludging of the tanks are available, and we estimate that in addition to these men the number of watermen required would be as follows :

TABLE VIII.

Class of soil and subsoil and method of working.	Number of watermen required.
Class I. Sub-class a. Filtration with cropping	One.
Class I. Sub-class b. Filtration with little cropping	One.
Class I. Sub-class c. Surface irrigation with cropping	Two.
Class II. Surface irrigation with cropping	Three.
Class III. Surface irrigation with cropping	Four

Taking labourers' wages as before at 21s. per week, together with two-thirds the manager's time, the cost of labour and supervision in respect of the distribution of sewage is as follows :—

TABLE IX.

Class of soil and subsoil and method of working.	Cost of labour and supervision in respect of distribution of sewage.	
	Per annum.	Per million gallons (dry weather flow).
	£	£ s. d.
Class I. Sub-class a. Filtration with cropping	141	0 7 8¾
Class I. Sub-class b. Filtration with little cropping	141	0 7 8¾
Class I. Sub-class c. Surface irrigation with cropping	196	0 10 9
Class II. Surface irrigation with cropping	250	0 13 8½
Class III. Surface irrigation with cropping	305	0 16 8½

219. The total cost of treatment, including loan charges and all other charges, is shown in Table X.

Table X.

Total Gross Cost of Land Treatment.

Class of soil and subsoil and method of working.	Per annum.	Per million gallons (dry weather flow).
	£ s. d.	£ s. d.
Class I. Sub-class a. Filtration with cropping	1,242 12 1	3 8 0¾
Class I. Sub-class b. Filtration with little cropping	908 9 5	2 9 9
Class I. Sub-class c. Surface irrigation with cropping	1,529 4 10	4 3 9¾
Class II. Surface irrigation with cropping	2,202 9 2	6 0 8½
Class III. Surface irrigation with cropping	3,129 0 8	8 11 5½

Returns from Sales of Crops.

220. In the case of land treatment of sewage, a part, frequently a large part, of the cost of treatment is defrayed by returns from sales of crops, stock, sludge, etc.

These returns necessarily vary at different farms, but we find from a careful study of the figures obtained at thirteen sewage farms, that the net return, after deducting cost of agricultural working, may be put at about 30s. per acre of the total area of the farm. We have therefore taken this figure for our calculations in the following Table :—

Table XI.

Class of soil and subsoil and method of working.	Returns from sales of crops.	
	Per annum.	Per million gallons (dry weather flow).
	£ s. d.	£ s. d.
Class I. Sub class a. Filtration with cropping	126 0 0	0 6 10¾
Class I. Sub-class b. Filtration with little cropping	60 0 0	0 3 3¼
Class I. Sub-class c. Surface irrigation with cropping	217 10 0	0 11 11
Class II. Surface irrigation with cropping	300 0 0	0 16 5
Class III. Surface irrigation with cropping	501 0 0	1 7 5

Total net Cost of Treatment.

221. Deducting the returns from sales of crops from the gross cost of treatment, we obtain the following figures for the total net cost of treatment :—

Class III. Surface irrigation with cropping	2,628 0 8	7 4 0

Comparative Cost of Treatment of Sewage by Land and by Artificial Processes.

222. Table XIII. shows the comparative cost of treatment of sewage by land and by artificial processes.

We wish to emphasize the fact that in the preparation of our "cost" tables, we have made a number of assumptions. and that the relative cost of different methods would, in practice, largely depend on local circumstances.

Table XIII.

Method of Treatment.	Total cost of treatment per annum.	Total cost of treatment per million gallons.	*Cost per head of population draining to works (population taken at 30,000).

*Based on a flow of 33 gallons of sewage per head per day.

Assuming that really suitable land can be purchased at £100 per acre, land treatment of sewage is probably cheaper than artificial treatment, but where the soil is not suitable, and on which only a comparatively small volume of sewage can be treated per acre, the cost of land treatment would probably be greater than most of the artificial processes.

The differences in cost are, however, small, and it is evident that, in deciding between the two methods, regard must be had to local conditions. If, for instance, £200 per acre had to be paid for land, the cost of land treatment would materially exceed the estimates given, which have been based on an assumed uniform price of £100 per acre.

As a general rule an effluent from good land, properly worked, contains practically no suspended solids, but this cannot be said of artificial filters, even assuming that settlement of the effluent in tanks is adopted. This might be a factor of considerable importance in the case of some streams.

The figures of cost in this section have been prepared by our Engineer, Mr. G. B. Kershaw.

PART IV.—SLUDGE.

DISPOSAL OF SEWAGE SLUDGE.

223. The disposal of sewage sludge, whether it is produced by settlement after chemical precipitation, settlement without chemicals, or septic tank treatment, is one of the chief difficulties in dealing with sewage, especially in the case of large towns or cities. Probably it will always remain so, excepting at small sewage works, for although sewage sludge contains small quantities of nitrogenous compounds and phosphates, and sometimes grease in sufficient quantity to repay extraction, by far the greater part of it consists, in addition to moisture, of mineral matters, together with some cellulose.

Conversion of Sludge into a Marketable Manure.

224. Two processes for converting sludge into a marketable manure have been under observation by us, viz.:—the production of "Native Guano" by the Native Guano Company, Limited, at Kingston-on-Thames, and the production of "Globe Fertilizer" by Mr. Melvin's process at Glasgow.

Kingston-on-Thames.

At Kingston a quantity of alumino-ferric, together with blood, charcoal, and clay is added to the sewage. This mixture acts as an extremely efficient precipitant, producing uniformly, from a sewage of about average strength, a tank liquor containing seldom more than two parts of suspended matter per 100,000. The sludge is removed from the tanks, pressed, partially dried by heat and sieved, and, after further air-drying during storage, is sold under the name of "Native Guano." The cost to the inhabitants of Kingston of the precipitation of the sewage and the disposal of the sludge * is 1s. 8d. per head per year. This is considerably less than it would be if a less expensive precipitation process were adopted and the sludge barged to sea. Further, although there is generally a slight peculiar odour of Native Guano upon the works, the treatment, so far we have observed it, has been free from nuisance.

It will be seen from the manurial experiments with sewage sludges, which are referred to later, and which were carried out for the Commission through the Board of Agriculture and the Royal Agricultural Society, during the seasons 1905–7,† that unit for unit the nitrogen and phosphate of the Native Guano were less effective, at all events within the limits of one season, than the same constituents applied in the form of ordinary artificial manure. Judged solely in this light, the price of the Native Guano is in excess of its direct manurial value. On the other hand, the books of the Company show that the manure is sold to the same farmers year by year. The manure appears to be used to a considerable extent for flower culture.

We doubt whether the process could be worked as a financial success if it were adopted at a *large* number of places, as, apart from the considerations which have just been mentioned, a greatly increased production of the manure would, we think, be certain to lower the price considerably.

It should be added, however, that the cost of the precipitation, and possibly also of other parts of the manufacture of the Native Guano, might, we think, be materially reduced by working on a large scale.

---

* This constituted the whole process at Kingston during the greater part of our observations. The figure 1s. 8d. per head refers to the precipitation and sludge disposal only. The precipitation liquor is now (1907) treated upon filters.

† Reports upon Experiments with various kinds of Sewage Sludges, as applied to mangolds, grass and cereals, by Dr. W. Somerville (1906), Mr. T. H. Middleton (1907), and Dr. J. A. Voelcker (1907), Appendix VIII.

A sample of Native Guano (A.), made up of eighty-five different fractions, was taken on March 23rd, 1905, and examined both chemically and bacteriologically. It was in a fine state of division. In the second column are given the figures of analysis of another sample of Native Guano (B.), examined partly in October, 1904, and partly in January, 1905. The following results were obtained :—

	A. Per cent.	B. Per cent.
Moisture (at about 110° C.)	25·87	10·19
Matter volatile on ignition	37·99	45·08
Non-volatile matter	36·14	44·73
	100·0	100·0

Analysis of Non-Volatile Matter.

	Per cent.	Per cent.
Grit (*i.e.*, matter insoluble in hydrochloric acid, after ignition)	22·33	28·04
Oxides of iron and alumina*	10·10	11·59
Lime†	3·30	4·78
Magnesia		0·42
Potash (soluble in dilute hydrochloric acid)	approx. 0·16	—
Potash (soluble in water)	0·06	—
Phosphoric acid (P_2O_5)	1·74§	2·35§
Equivalent to tribasic phosphate of lime	3·30	5·13
Yield of Nitrogen (total)	1·93‖	2·49‖
Nitrogen evolved as ammonia on boiling for 2 hours with a dilute solution of potash (0·5 per cent. KOH)	0·41	0·50

Allowing for the difference in moisture, the above two samples have almost the same composition, but B. is slightly richer in nitrogen and phosphoric acid than A.

Bacteriological Analysis.—Sample A.

Kingston "Native Guano." Average of eighty-five samples, March 23rd, 1905.

B. Coli Test.—Negative result with 1 gramme.

Neutral Red Broth Test.—As regards fluorescence, positive with 1–1,000 ; negative with 1–10,000 of a gramme. Growth in tube inoculated with 1–10,000,000,000 of a gramme, indicating the survival of an enormous number of bacteria.

B. Enteritidis Sporogenes Test.—Positive result with 1–1,000 ; negative with 1–10,000 of a gramme.

Glasgow (Dalmarnock).

225. Mr. Melvin's process at Glasgow for the production of the "Globe Fertiliser" is somewhat similar to the process for the production of Native Guano. The sludge is produced from the Glasgow (Dalmarnock) sewage by precipitation with lime and ferric sulphate. After removal from the tanks it is pressed, and that part of it which is to be converted into Globe Fertiliser is then artificially dried at a temperature of about 65° to 70° C., and finally passed through a pan-mill. It issues from the latter as a moist brown powder, which is given the name of "Globe Fertiliser." An average sample of this, collected on April 6th, 1905, gave the following figures on analysis :—

	Per cent.
Moisture (at about 110° C.)	22·51
Matter volatile on heating	33·98
Non-volatile matter	43·51
	100·0

* These oxides will contain the phosphoric acid and possibly a very little of the lime.

† The lime was precipitated only once ; it will contain traces of magnesia.

§ ‖ The figures for phosphoric acid and for total nitrogen are in each case the mean of two closely agreeing estimations.

Analysis of Non-Volatile Matter.

	Per cent.
Grit, etc. (*i.e.*, matter insoluble in hydrochloric acid, after ignition)	10·75
Oxides of iron and alumina*	13·42
Lime†	12·09
Magnesia	—
Potash (soluble in hydrochloric acid)	approx. 0·10
Phosphoric acid ($P_2 O_5$)	1·11‡
Equivalent to tribasic phosphate of lime	2·42
Yield of Nitrogen (total)	1·30‖
Nitrogen evolved on boiling the sludge for 2 hours with dilute (0·5 per cent.) potash solution on May 22nd [1]	0·06

([1] Grey mould on surface, at this date, which was avoided in sampling).

Bacteriological Analysis.

Glasgow, "Globe Fertiliser." Average of twenty samples.

B. Coli Test.—Negative result with 1 gramme.

Neutral Red Broth Test.—As regards fluorescence, positive result with 1–1,000; negative with 1–10,000 of a gramme. Growth in 1–100,000; no growth in 1–1,000,000 of a gramme.

B. Enteritidis Sporogenes Test.—Positive result with 1–100; negative with 1–1,000 of a gramme.

A larger portion of the sludge is converted into pressed cake, without being artificially dried.

The following table shows the production and sale of Globe Fertiliser and pressed cake at the Glasgow (Dalmarnock) works during the five years ending March, 1907 :—

Aggregate Quantities of 5 Years' Working.

Total amount of wet sludge dealt with. (Tons).	Total amount of pressed cake produced. (Tons).	Total amount of pressed cake sold to farmers. (Tons).	Total amount of Globe Fertiliser produced. (Tons).	Total amount of Globe Fertiliser sold to Customers. (Tons).
1,104,297 (Moisture 91% approx.).	177,566 (Moisture 60 to 65%).	124,883	5,702	5,703

Mr. Melvin gives the costs relating to these figures (excluding interest and sinking fund), as follows :—

Cost of pressing alone, per ton of pressed cake.—2s. $0\frac{5}{10}$d.

Cost of production of Globe Fertiliser, approximately.—5s. 6d. per ton, excluding pressing of wet sludge.

Total cost of production of Globe Fertiliser, approximately.—10s. per ton.

The average price obtained for the pressed cake was 8d. to 1s. per ton in bulk; the average price for the Globe Fertiliser 8s. to 10s. per ton in bulk, or 14s. per ton in bags. The purchaser pays the carriage in all cases.

---

* These oxides will contain the phosphoric acid and possibly a very little of the lime.

† The lime was precipitated only once; it will contain traces of magnesia.

‡ ‖ The figures for phosphoric acid and for total nitrogen are in each case the mean of two closely agreeing estimations.

The analyses of the pressed cake and Globe Fertiliser are given by Mr. Melvin as follows :—

	Pressed Cake. Per Cent.	Globe Fertiliser. Per Cent.
(1) Organic Matter	13·84	35·20
(2) Mineral Matter	18·16	46·20
Moisture	68·00	18·60
	100·0	100·0
(1) Containing Nitrogen	·52	1·34
Equal to Ammonia	·64	1·63
Or Sulphate of Ammonia	2·49	6·33
(2) Containing Phosphoric Acid	·54	1·39
Equal to Tribasic Phosphate of Lime	1·19	3·03
Analysis Value	6s. 11d. per ton.	17s. 8d. per ton.

It will be seen, therefore, that at Dalmarnock, by careful organisation and advertising, practically the whole of the sludge is disposed of by sale, either as pressed cake or as Globe Fertiliser, the cost of the sewage treatment being in this way materially reduced. The saving effected is about 4s. per 1,000,000 gallons. During the three years ending March 31st, 1907, the whole of the pressed cake was sold to farmers. The demand is still increasing and the connection is now good enough to obviate the necessity for advertising.

Mr. Melvin states that it is more convenient to sell sludge as pressed cake than as Globe Fertiliser, partly because less work is entailed in the former case, and partly because in the manufacture of the Fertiliser much dust is produced, and he finds it difficult to get his men to wear respirators. For this reason, the Globe Fertiliser is now made during spring and autumn only, and the quantity is diminishing year by year.

In comparing the sale of pressed cake at the Dalmarnock works with sales and possibilities of sales elsewhere, it has to be specially noted that there is a branch line of railway into the Dalmarnock works, and therefore no carting is required.

Disposal of Sludge by Depositing at Sea.

226. There can be little doubt that, for cities on or near the sea-board, the disposal of sludge by taking it to sea is, in the majority of cases, the cheapest process.

Except, however, in the case of the Barrow Deep, where the London sludge is discharged, little attention appears to have been paid to the effect of the sludge upon the character of the water in the neighbourhood of the dumping area. In order to avoid nuisance and possible danger to health from the pollution of shell-fish, periodical examination of the local conditions is generally desirable wherever this method of disposal is adopted.

London.

18, 502 *et. seq.* (Fourth Report, Vol II.)

227. The plan adopted for the disposal of the London sludge was fully explained to us by Mr. M. Fitzmaurice, C.M.G., when giving evidence on July 14th, 1903.

It will be seen from the evidence that the sludge is deposited at the Barrow Deep, over a length of from five to ten miles.

The Barrow Deep is practically the open sea, being situated about 20 miles below Southend.

The following table, which has been more recently supplied to us by Mr. Fitzmaurice, shows the quantity of wet sludge, etc., deposited in the Barrow Deep during the years 1903, 1904, 1905 and 1906 :—

County of London.

Year.	Average daily quantity of sewage dealt with. (Gallons.)	Total quantity of sludge produced at Barking and Crosness. (Tons.)	Average percentage of moisture in the sludge.	Total quantity of sludge sent to sea (Tons.)	Number of trips made by the steamers.	Total cost of sending to sea, per ton of wet sludge; interest, sinking fund, steamer dues, cost of filling ships and all charges included.†
1903	259,769,466	2,563,000*	92·02%	2,563,000*	2,563	4·51d.
1904	250,590,204	2,530,000	92·28%	2,530,000	2,530	4·77d.
1905	250,698,649	2,578,000	92·16%	2,578,000	2,578	4·40d.
1906	252,882,247	2,465,000	91·95%	2,465,000	2,465	4·53d.

The average cost of sending the London sludge to sea during the years 1903 to 1906 inclusive, including interest, sinking fund, cost of filling ships, labour, fuel, repairs and all charges, was thus 4·55d. per ton of sludge containing on the average 92·1 per cent. of moisture.

228. At our request Mr. Fitzmaurice carried out some float experiments in the Barrow Deep during spring and neap tides in September, 1903. These experiments showed that, with the exception of a slight set towards the Maplin Sands at flood tide, both the ebb and the flow took a course directly along the Barrow Deep. We note, however, that floats started at the most westerly point at which the steamers begin to discharge sludge were carried back on the flood tide nearly as far as the Nore Lightship. The experiments are shown graphically in the Fourth Report of the Commission, Vol. II., p. 106.

With regard to the condition of the water in the Barrow Deep, we may refer to the evidence of Professor F. Clowes, D.Sc., F.I.C. As the result of the examination of four series of samples collected in the Barrow Deep, Dr. Clowes makes the following *Statement of Conclusions* :— Clowes, 18,636.

> " A study of these tables shows that there are on an average over 100,000,000 " of bacteria per cubic centimetre in the sludge discharged by the Council's steamers " in the Barrow Deep, and that about half this number are probably of intestinal " origin, since they are capable of growing at blood heat (37° C.); but that " immediately after the discharge of the sludge the number in the water of the " Barrow Deep is less than 2,500 per cubic centimetre, and that the number of " intestinal bacteria is generally less than 10 per cubic centimetre; indicating a " reduction of about 99·9 per cent. in the total number of bacteria and of intestinal " bacteria. Further, that the number of bacteria in the water which is carried out " of the Barrow Deep towards the mouth of the Thames, by an incoming flood tide, " is still further reduced to an average of 440 per cubic centimetre, and that the " number of intestinal bacteria has also further decreased."

The results of two experiments by Dr. Clowes upon the effect of sea water on bacterial life appear, so far as they go, to indicate that sea water does not exercise any marked inhibitory effect upon the life of the bacteria. On this showing, therefore, the above decrease in the number of bacteria in the Barrow Deep must evidently be looked upon as due to mere dilution of the sludge with sea water.

* The quantity of sludge produced per annum may be slightly different from the quantity sent to sea per annum, as a certain amount of sludge is sometimes in store at the end of one year but not sent to sea until the beginning of the following year. This difference is not shown in the above table.

† The cost of filling the ships with sludge cannot be stated separately.

Examination of the Sands in the Barrow Deep and the Thames Estuary.

Clowes 18,636. 229. In August, 1899, Dr. Clowes made a chemical and microscopical examination of samples from the sea bottom in the part of the estuary where the sludge is deposited, and in parts of it which might be affected by the sludge. His conclusions are given as follows :—

> "The results of these examinations of the sands and of the deposits in the "Barrow Deep and in other channels in the estuary of the River Thames, during "the period 2nd to 12th August, 1899, show that no sludge is carried by the tide "beyond the limits of the Barrow Deep and the Oaze Deep in a westerly or "up-river direction. The sludge which is carried in an easterly or seaward "direction must meet with so great a volume of sea water that it is quickly broken "up into innocuous bodies, and thus prevented from travelling beyond the Barrow "Deep. Accordingly no evidence of pollution by sludge was obtained in an "easterly, northerly, or southerly direction."

The subject of sea water in relation to bacteriological life is more complicated than would appear at first sight, and before conclusions can be drawn with confidence as to the effects of deposition of sludge, observations extending over a lengthened period and under a variety of conditions would, we think, be required.

Taken in conjunction with Mr. Fitzmaurice's float experiments, the above results furnish grounds for the presumption that the polluted water is for the most part carried out to the open sea on the ebb tide ; but conclusively to prove that none of it returns with the flood, extensive experiments covering the whole area of the Thames estuary would be necessary.

Glasgow.

230. There are at present (1907) two outfall works at Glasgow—the Eastern or Dalmarnock outfall and the Western or Dalmuir outfall. As has previously been said, the whole of the sludge at Dalmarnock is pressed and disposed of to farmers, either as pressed cake or as Globe Fertiliser. At Dalmuir, with the exception of the grit from the catch pit and the screenings of the sewage, both of which are mostly disposed of by sale to farmers at a price of about 8d. to 1s. per ton., plus railway carriage, the whole of the sludge is taken by the s.s. "Dalmuir," and discharged in about 80 fathoms of water some three miles below Garroch Head, a distance of about forty miles from Glasgow.

The following figures, which have been supplied to us by Mr. Thomas Melvin, relate to the disposal of sludge at Dalmuir for the three years subsequent to the opening of the works in May, 1904 :—

Aggregate Quantities for the 3 Years Ending March 31st, 1907.

Total quantity of sludge produced by precipitation. (Tons).	Average percentage of moisture.	Total quantity deposited at sea. (Tons).	Average number of journeys made per annum by the s.s. "Dalmuir."	Average cost of sending sludge to sea, including all charges except interest and sinking fund and cost of filling ships, per ton of wet sludge.	Average cost, per ton of wet sludge, of handling the sludge after it leaves the precipitation tanks, *i.e.*, the cost of filling the ship.*
915,689	86·81%	915,689	268	$2\frac{5}{10}$ d. full.	$0\frac{9}{10}$ d. full.

The cost of sending the sludge to sea during the year 1906–7, including the cost of filling the ships and the interest and sinking fund for the same period, was $5\frac{4}{10}$d. per ton, for 349,492 tons of sludge containing 85·54 per cent. of moisture. This includes interest and sinking fund on a specially constructed dock, as well as upon the steamer. The loan for the dock and the steamer is repayable, however, in equal instalments extending over the long period of sixty years. If it were repayable in thirty years, the above cost would be approximately $6\frac{2}{10}$d. per ton.

*This includes the cost of fuel for the electrically driven pumps which lift the sludge into the overhead reservoir tank.

Through the courtesy of the Glasgow City Corporation one of our officers was enabled to witness the discharge of sludge into the sea on November 20th, 1907. When the steamer reached a position about 3 miles S.S.W. of Garroch Head, between the Island of Arran and the mainland, the engines were stopped, and while the steamer continued to move slowly, she was turned so as to describe a half-circle of about $\frac{1}{4}$ of a mile in diameter. All the sludge valves were open during this time (about five minutes), the whole of the sludge being thus discharged. From the bridge of the steamer the sludge could be seen just below the surface of the clear water as a thick brown cloud. It rose to the surface behind the steamer, appearing from a distance as a band of smooth water some 20 or 30 yards wide. Many thousands of gulls which had followed the steamer immediately settled upon this. On turning and passing through the sludge band, after about eight minutes had elapsed since the steamer first began to discharge, it was seen that the band had widened considerably; and after 15 to 20 minutes, during which another turn was made, the sludge was still easily visible, though more disseminated. Probably it disappears entirely in the space of half-an-hour. The impression produced on the observer was that, even with the small tide of two knots an hour, everything but the very heavy solids would be spread over a very large area before reaching the bottom. The depth of the water was about 76 fathoms. We were informed that the tides run straight up and down the Firth, part of the incoming tide flowing between Bute and Little Cumbrae and part turning to the left towards Kilbrennan Sound. No analyses of the water in the neighbourhood of the dumping area have been made by the Local Authorities. We were told that the water in the neighbourhood of the dumping area is a favourite fishing ground.

Manchester.

231. The sludge produced at the Manchester sewage works (Davyhulme) is taken by steamer through the Manchester Ship Canal and deposited in deep water outside the North-west lightship. The lightship is situated in the open sea some 12 miles north of Rhyl and about 25 miles north-west of Liverpool.

The following figures, relating to the disposal of the Manchester sludge during the past five years, have been supplied to us by the Rivers Department of the City of Manchester.

Year ending March 31st.	Nature of sludge.	Total quantity of wet sludge produced. (Tons).	Total quantity of wet sludge sent to sea. (Tons).	Average percentage of moisture in the sludge.	Number of trips made by the steamer.	Total Sea Cost :—			
						Excluding interest and sinking fund charges, and also cost of filling ship.		Including interest and sinking fund charges (onsteamer), but excluding cost of filling ship.‡	
						Per annum.	Per ton of wet sludge.	Per annum.	Per ton of wet sludge.
1903	Chemical precipitation (mainly) and septic tank sludge	223,100	223,100	—	181	£5,283	5·7d.	£7,273	7·8d.
1904	Chemical precipitation and septic tank sludge	157,100	157,100	*85·0	129	£4,366	6·6d.	£6,356	9·7d.
†1905	Sedimentation and septic tank sludge	148,100	143,800	*85·4	123	£3,994	6·7d.	£5,984	10·0d.
†1906	Do.	155,800	142,200	86·1	136	£4,976	8·4d.	£6,966	11·8d.
†1907	Do.	181,600	176,300	86·7	163	£4,758	6·5d.	£6,748	9·2d.
	Total for 5 years -		842,500			Average	6·7d.	Average	9·5d.

* Percentage of water in septic tank sludge only.

† During these years the sludge steamer also ran on behalf of the Salford Corporation, making the following additional number of journeys :—1905, 44 ; 1906, 36 ; 1907, 25.

‡ Cost of filling ship, including sludge tank attendant, ejector attendant, repairs to ejector, and also including steam production, engines, and interest and sinking fund charges :—
Average—£123 per annum = 0·14d. per ton of wet sludge.

Salford.

232. The sludge from the Salford Corporation Sewage Works at Weaste is also sent through the Manchester Ship Canal and deposited outside the North-west lightship. The following figures, which have been supplied to us by Mr. J. Corbett, the Borough Surveyor, relate to the disposal of the Salford sludge for the years 1902–6 inclusive :—

Year.	Total quantity of sewage dealt with. (Gallons).	Total quantity of sludge produced and sent to sea. (Tons).	Average percentage of moisture in the sludge.	Number of journeys made by steamer.	Total cost, per ton of wet sludge, of sending to sea, including interest and sinking fund, canal dues, cost of filling ship and all other charges.
1902	3,802,182,451	129,000	80·2	215	
1903	3,989,619,000	135,000	78·6	225	
1904	3,335,080,548	134,900	79·5	199	
1905	3,782,877,000	134,900	75·4	184	
1906	4,227,950,000	145,400	81·0	191	
			Average for the five years		9·46d. per ton.

Note.—The percentage of water in the Salford sludge was exceptionally low during the years in question, owing partly to the fact that some old air-dried sludge which had accumulated on the works was mixed with the fresh sludge from the tanks. This had, of course, the effect of reducing the cost of sea disposal per ton.

Dublin.

233. At Dublin the whole of the sludge produced by the precipitation of the sewage with lime is taken to sea in the "s.s. Shamrock" and deposited in about 90 feet of water, some 2 miles N.E.E. of the Bailey Light on Howth. The following figures, which have been supplied to us by Mr. Spencer Harty, show the cost of disposal :—

The figures refer to the year ending October 22nd, 1907.

Total quantity of sewage treated during the year. (Gallons).	Average daily quantity of sewage dealt with. (Gallons).	Total quantity of sludge produced. (Tons).	Percentage of water in sludge.	Total quantity of sludge sent to sea. (Tons).	Number of trips made by steamer.	Cost of sending sludge to sea, including all charges,* except the cost of filling the ship and interest and sinking fund on steamer. (Per ton of sludge.)	Cost of filling ship from sludge reservoir. (Per ton of sludge.)	Total cost of sending sludge to sea, including cost of filling ship, interest and sinking fund on steamer† and all other charges.* (Per ton of sludge.)
4,829,000,000	13,230,000	114,560	90 % (approx).	114,560	320	3·47d.‡	0·049d.	5·02d.

* In the case of Dublin no harbour dues are payable; the Corporation are the owners of Pigeon House Harbour.

† The average interest and sinking fund on the cost of the steamer (£11,139) is given as follows :—

Average sinking fund	£146
Average dividend	£362
Total	£508

The loan for the steamer is included in the loan for the entire main drainage works, and is repayable in 39 years.

‡ In this figure is included an item of £196 6s. 0d. for ropes, ironmongery, uniforms, lamps, clock, bedding, etc. The vessel is a new one, and this was her first equipment. The figure 3·47d. is somewhat high on this account.

Southampton.

234. At Southampton the sludge from the sedimentation tanks is pumped into a barge which is then towed by way of Spithead to a position 3 miles from land, when the sludge is discharged. The operation is carried out by contract, the Corporation paying 1s. 2d. per cube yard of sludge. The contractor supplies the barge and the tug. The capacity of the barge is 114 cube yards. The following figures relating to Southampton have been supplied by Mr. J. A. Crowther:—

The figures refer to the year ending March, 1907.

Total quantity of sludge sent to sea.	Percentage of moisture in the sludge.	Number of journeys made by tug with barge.	Cost of disposal, excluding cost of filling barge and interest and sinking fund on pumping machinery.
16,896 cube yards or about 13,950 tons.*	about 90.	149	1s. 2d.† per cube yard or about 1s. 4·9d.* per ton.

* These are calculated figures; they are only approximate.
† This is the contract price.

235. SUMMARY OF FIGURES RELATING TO COST OF SEA DISPOSAL.

A. Place.	B. Year or years to which the figures refer.	C. Average annual quantity of sludge deposited at sea. (Tons).	D. Average percentage of water in sludge actually deposited.	E. Total cost of sea disposal, including cost of filling ship, interest and sinking fund, steamer dues and all other charges. (Per ton of sludge actually deposited.)	F. Total cost of sea disposal, including cost of filling ship, interest and sinking fund, steamer dues and all other charges. (Per ton of *dry solid matter*.)	G. Total cost of sea disposal, including cost of filling ship, interest and sinking fund, steamer dues and all charges; calculated as per ton of sludge containing 90 per cent. of water.	H. Remarks.
Glasgow -	1906-7.	305,000	86·8	5·40d.	40·9d.	*4·1d.	Large quantity of thick sludge. Loan repayable in 60 years.
Salford -	1902, 3, 4, 5, and 6.	136,000	79·0	9·45d.	45·0d.	*4·5d.	Heavy canal dues. Very thick sludge.
Dublin -	1906-7.	114,560	90·0 ap.	5·02d.	50·2d.	*5·0d.	No harbour dues and short distance to dumping area.
London -	1903, 4, 5, and 6.	2,534,000	92·0	4·55d.	56·9d.	*5·6d.	Very large quantity, but thin sludge.
Manchester-	1903, 4, 5, and 7.	168,500	86·0 ap.	9·64d.	68·9d.	*6·9d.	Heavy canal dues.
Southampton	1906-7.	13,950	90·0 ap.	16·9d.	169·0d.	16·9d.	By contract.

* These are figures obtained by calculation, on the assumption—which is probably not quite correct—that it is as easy to deal with dense as with liquid sludge. There would probably be more wear and tear of machinery in the case of dense sludge, but on the other hand the same amount of solid matter in the form of liquid sludge might mean more steamer capacity. The figures in column G. must therefore be taken as giving only an approximate idea of comparative costs.

Pressing of Sludge.

236. The plan of pressing sludge is adopted at a large number of places. Strictly speaking, it is not a method of disposing of the sludge finally; but at by far the greater number of places where pressing is done, it has the effect of converting the sludge into a form in which it can either be sold to farmers for a return of something like 6d. per ton, or can be tipped or buried without serious expense. For this reason it may generally be considered an effective means of disposing of sludge.

Very briefly, the plan is as follows:—The sludge produced by the settlement of the sewage, with or without the addition of chemicals, is first run, or pushed by hand labour, from the settling tanks into a sludge well or tank. In this well it is allowed to settle for some little time, and, after the supernatant liquor has been drawn off, the thick sludge is mixed with from 0·5 to 1 per cent. of lime (or even more) in the form of milk of lime and then forced by means of compressed air into filter presses. In this way, on the average, something like 30 or 35 per cent. of the water in the wet sludge (which may be taken at approximately 90 per cent. on the average) is removed, leaving a moist but solid cake which may contain from 50 to 65 per cent. of water. The liquid pressed from the sludge is run back into the settling tanks for re-treatment. It is strongly alkaline, owing to the lime which has been added to the wet sludge. The pressed cake is scraped from the press-cloths into trucks and either sold to farmers, buried, or tipped. The cost of the process, excluding interest and sinking fund in respect of the pressing plant, may be put at from 2s. to 5s. per ton of pressed cake produced. As will be seen from the appended table, however, it varies largely at different places, depending mainly upon:—

(*a*) The amount of lime added to the sludge;
(*b*) The kind of sludge pressed;
(*c*) The size of the works at which the plan is adopted.

The variation in cost, dependent upon the kind of sludge to be pressed and the amount of lime to be added, is readily seen from the table.

As regards the variation in cost, dependent upon the kind of sludge to be pressed, it may be pointed out that the solid matter in septic tank sludge, especially in sludge from a tank which has been in use for a long time (say, a year) without cleaning, is generally in a very fine state of division. For this reason, a large quantity of lime has usually to be added to it, in order to prevent the press-cloths becoming clogged. At Hanley, it is true, only a very small amount of lime is used, but the septic tanks are cleaned out at short intervals (once every month), and there is a considerable quantity of "clay slip" in the sewage, which apparently helps the settlement and possibly delays the putrefaction of the sludge in the septic tanks. It is to be noted also that the milk of lime is added hot at that place.

At Nelson and at Burnley, where septic tank sludge is pressed, the quantities of lime added are respectively 9·6 per cent. and 15 per cent. of the pressed cake, and the cost of pressing, excluding interest and sinking fund, is 4s. 6·9d. and 4s. 3·4d., respectively. At Rochdale it was found necessary to add at least twice as much lime to the septic tank sludge as was required for the pressing of the chemical precipitation sludge, viz., 10 per cent. as against 5 per cent., calculated on the pressed cake. At York, so much lime had to be added to the septic tank sludge, in comparison with the amount required for the treatment of sludge from precipitation tanks, that the process was abandoned as being prohibitively costly.

22,630. We may refer also to the evidence given by Dr. James B. Wilkinson, who said that at Oldham they had found great difficulty in pressing the sludge from septic tanks.

In some cases, unusually large quantities of lime are added to precipitation sludge before pressing, but this is where manufacturing waste of a greasy nature finds its way into the sewers, or where, as in the case of Ealing, a specially hard cake is made, in order

COST OF PRESSING SLUDGE.

In all cases, unless otherwise stated, the cost of pressing is taken as beginning when the sludge is out of the sedimentation tanks and is ready to be pumped into the presses. The cost of sludging the sedimentation tanks is not included. The cost of pressing is taken as ending when the pressed cake is in the trucks below the presses.

A	B	C	D	E	F	G	H	I	J	K	L
Place.	Year to which the figures refer.	Population.	Kind of sludge pressed.	Proportion of lime added to the sludge for the purpose of pressing; stated as per cent. of :—		Cost of pressing the sludge, including labour, fuel, lime, press-cloths, repairs and renewals, but excluding interest and sinking fund on pressing plant.		Cost of pressing the sludge, including labour, fuel, lime, press-cloths, repairs and renewals, *and also* interest and sinking fund on pressing plant.		How the pressed cake is disposed of.	Remarks and Notes.
				(a) The wet sludge.	(b) The pressed cake.	(a) Per ton of wet sludge.	(b) Per ton of pressed cake.	(a) Per ton of wet sludge.	(b) Per ton of pressed cake.		
Hanley	1907	66,000	Septic tank and detritus tank sludge	0·35%	1·43%	4·75d.	1s.7d.	5·75d.	1s. 11d.	Tipped at the works.	At Hanley the milk of lime is added hot to the sludge, as the latter is pumped into the sludge well. The mixture is then allowed to stand for several days before pressing. The septic tanks are cleaned out once a month.
Glasgow (Dalmarnock)	1906–7	300,000	Chemical precipitation sludge.	0·416%	2·50%	3·9d.	1s. 11·6d.	4·66d.	2s. 4d.	The pressed cake is sold to farmers at 8d. to 1s. per ton in bulk. The farmer pays carriage.	
Leyton	1906–7	120,000	Chemical precipitation sludge.	0·75%	3·75%	4·80d.	2s.	—	—	For some time past the greater part of the pressed cake has been burnt in a refuse destructor, the remainder being given away to farmers. This year (1907) the Authorities are entering into a short agreement with a contractor to load up the cake into trucks on the railway adjoining the works, the contractor to pay 6d. per ton for the cake in the trucks.	
Stockport	1906–7	91,500	Chemical precipitation sludge.	0·85%	3·25%	6·26d.	2s. 0·02d.	7·91d.	2s. 6·31d.	Given away to farmers.	
Wolverhampton	1906–7	101,000	Chemical precipitation sludge.	0·49%	2·10%	5·63d.	2s. 0·28d.	6·48d.	2s. 3·94d.	Partly by tipping (56 per cent.) and partly by barging to farmers. In the latter method of disposal the cake is conveyed in the Corporation barges to the farmers, at a nominal charge of £1 per boat load. This does not always cover the cost of conveyance and upkeep of boats, etc. The average loss is 1s. 2d. per boat-load of 2 tons, or 0·73d. per ton of cake.	
Bolton	1906	170,000	Chemical precipitation sludge.	1·12%	5·6%	5·4d.	2s. 2·9d.	10·2d.	4s. 2·9d.	Removed by farmers, the Corporation paying 3d. per ton of pressed cake.	
Bury	1906–7	50,000	Chemical precipitation sludge.	0·67%	3·62%	5·2d.	2s. 4d.	—	—	Given away to farmers free of charge. Assistance is given in loading.	The figures of cost for Bury include the cost of sludging the precipitation tanks. This addition to the cost is very small, however, as it involves the labour of only one man.
Richmond (Surrey)	1907	62,885	Chemical precipitation sludge with some septic tank sludge.	1·0% ap.	5·0% ap.	5·6d.	2s. 4d.	7.2d.	3s.	The pressed cake is tipped into barges and taken away by a contractor who supplies the barges. It is sold by him to farmers in Essex and Kent. The cost to the Richmond Main Sewerage Board in 1907 was 1s. 9d. per ton of pressed cake or 4·25d. per ton of wet sludge.	With regard to the capital expenditure, it should be noted that the engine plant and machinery is in duplicate. The plant is only worked one shift of 10 hours per day; if it were worked in two shifts, the cost of pressing, including interest and sinking fund, would be 6·4d. per ton of wet sludge, or 2s. 8d. per ton of pressed cake.
Hyde	1903	32,000	Chemical precipitation sludge.	1·25%	3·75%	10d.	2s. 6d.	1s. 3·3d.	3s. 10d.	Removed by farmers, free of cost, with the exception of a surplus quantity, for which 9d. per ton was paid to clear it away.	The figures of cost for Hyde include the cost of tank sludging. This is a small item, however, and only raises the cost very slightly.
Great Harwood	1906–7	22,500	Chemical precipitation sludge.		3·0%	—	2s. 6·2d.	—	3s. 7·2d.	Sold to farmers at 6d. per ton.	
Chorley	1906–7	26,500	Chemical precipitation sludge.	0·42%	4·25%	3·21d.	2s. 8·2d.	—	—	By sale to farmers: tons cwts. 1s. 6d. per 1-horse load = about 1 10 1s. 9d. per 2-horse load = about 2 0	
Wimbledon	1906–7	52,500	Chemical precipitation sludge.	1·0%	5·0%	7·25d.	3s. 1d.	8·75d.	3s. 7·75d.	By burying and burning.	
Royton	1906–7	12,500	Chemical precipitation sludge.		4·14%	—	3s. 2d.	—	4s. 1d.	Given away to farmers, who remove it themselves.	The figures of cost for Royton include the cost of sludging the tanks. This item is small, however, and against it must be put the fact that the steam required for the pressing is raised by Destructor fire. The cost of coal is included in the figures, but coal is only used to assist in raising the steam.
Leigh and Atherton	1906–7	63,600	Chemical precipitation sludge.	—	4·3%	—	3s. 4·98d.	—	4s. 1·58d.	Part deposited on portions of sewage farm not used for sewage treatment, and part sold to farmers at a present price of 1s. per 1-horse load and 1s. 6d. per 2-horse load. This is about 6d. per ton on the average.	The figure for cost of pressing, including interest and sinking fund, is estimated.
Middleton	1906–7	25,600	Settling tank sludge	0·67%	4·6%	6·5d.	3s. 7d.	7·5d.	4s. 1d.	Given away to farmers.	
Willesden	1905, 6 and 7	66,000	Chemical precipitation sludge.	2·2%	13·35%	8d.	3s. 9.2d.	8·58d.	4s. 0·78d.	Mostly by tipping on the sewage farm. During the early part of the present year (1907), however, a portion of the pressed cake has been disposed of to farmers, who have paid the cost of the railway freight only, the Council paying the cost of the carriage to the railway station.	The large percentage of lime used in the pressing of sludge at Willesden is due to the fact that the sewage there contains much laundry waste, and is of a rather greasy character.
Burnley	1905–6	80,000	Septic and detritus tank sludge.	3·4%	15·5%	12·85d.	4s. 3·45d	1s 1·96d.	4s. 7.91d.	Sold at the sewage works to farmers for 10d. per ton.	
Colchester	1906–7	41,000	Chemical precipitation sludge.	2·8%	11·2%	12·75d.	4s. 3·5d.	1s. 3·25d.	5s. 1d.	The pressed cake is disposed of to farmers at a price of 1s. per cart-load.	
Ealing (Southern Works)	1906–7	40,000	Chemical precipitation and settling tank sludge.	5·0%	20·0%	10·4d.	4s. 4d.	11·70d.	4s. 10·5d.	The cake is dropped into trucks and conveyed by hydraulic lift to refuse destructors, where it is burnt.	The sludge is pressed specially well at Ealing, on account of the subsequent burning.
Maidenhead	1906–7	14,000	Chemical precipitation sludge.	—	4·2%	—	4s. 4·1d.	—	—	All the pressed cake and also a fair proportion of air-dried sludge is sold to farmers and market gardeners at 6d. per cart-load.	
Nelson	1906–7	37,000	Septic and settling tank sludge.	—	9·6%	—	4s. 6·9d.	—	6s. 0·4d.	Given away to farmers.	The labour cost in connection with the sludge pressing is estimated.

To face page 168.

that it may subsequently be burnt. Generally speaking, there is no difficulty in pressing the sludge from precipitation or sedimentation tanks. It may be pointed out that the sludge from simple sedimentation requires, as a rule, the addition of more lime than the sludge derived from sedimentation after precipitation with chemicals; this is indicated in the table.

It may be useful to add here that success in pressing, whatever kind of sludge is being dealt with, depends very largely upon the intimate mixture of the milk of lime and the sludge. The dissolved lime has the effect of agglomerating the solids of the sludge, while the fine particles of undissolved lime, becoming interposed between the sludge particles, apparently provide small channels for the escape of the water. We may also mention that at York, Mr. Graham, the manager of the Sewage Works, found it useful to allow a small quantity of milk of lime to pass into the presses before the sludge, as the thin coating of solid lime thus formed on the press-cloths facilitated the subsequent pressing of the sludge and the removal of the cake.

Nuisance from Smell.

237. Speaking generally, properly pressed sludge when in the form of a solid cake does not give rise to serious nuisance from smell, and if exposed to the air in dry weather, it soon becomes entirely inoffensive. It has, however, a slight smell of fresh sewage, and if kept moist, *e.g.*, if it is exposed to the air during wet weather, it soon becomes putrid and gives rise to offensive odours. For this reason it should, if possible, be stored under cover, until it can be spread over land or dug into trenches or buried. At York, where a large quantity of pressed cake was tipped in the open, considerable nuisance is said to have arisen until Mr. Creer, the city engineer, adopted the plan of burying it, 5 or 6 feet thick, under a thin layer of soil and turf, when the nuisance entirely ceased. Incidentally, an uneven field is being levelled in this way.

Since there is almost always serious nuisance inside the press house, it is necessary that the house should be properly ventilated. It should also be situated as far as possible from any habitation, if complaint of nuisance is to be avoided.

Disposal of the Pressed Cake.

238. Pressed sludge can usually be disposed of to neighbouring farmers at about 6d. per ton. This, however, depends to a considerable extent upon the district in which the sewage works are situated. In some cases, *e.g.*, at Bury, Ealing (Northern Works), Wolverhampton, and Richmond, where the works are situated in densely populated districts, or are far removed from a railway, or in the case of a large town where the amount of sludge is greater than the neighbouring farmers require, the pressed cake has to be given away, or a small fee has to be paid for its removal.

The form of the pressed cake also affects its saleability; *e.g.*, at Burnley, where the Corporation break up the pressed cake immediately after pressing, a ready market is now obtained.

Composition of Pressed Cake.

239. The following figures of analysis give the chief mineral constituents and the nitrogen in the pressed cake from Chorley (Lancashire) and Dorking (Surrey), after complete drying at 110° C. These may be taken as more or less typical for domestic sewage, but there is more than the average quantity of lime in the Dorking pressed cake. The Chorley sludge is produced by the addition of about 9 grains per gallon of alumino-ferric to a sewage which is almost entirely domestic in character and of about average strength. The Chorley drainage area is sewered on the combined system. The Dorking sludge is obtained by the addition of about 5 grains per gallon of lime to a sewage of rather over average strength, and which, except for a small quantity of

brewery waste, is also almost entirely domestic in character. Dorking is sewered on the partially separate system.

	Chorley pressed cake after drying at 110° C. Sample drawn in April, 1905.	Dorking pressed cake after drying at 110° C. Sample drawn in April, 1905.
Grit, etc. (*i.e.*, matter insoluble in hydrochloric acid, after ignition)	25·30	6·84
Oxides of iron and alumina *	9·37	3·46
Lime †	10·32	23·16
Phosphoric acid (P_2O_5) ‡	0·98	0·66
Equivalent to tribasic phosphate of lime	2·14	1·44
Nitrogen (total) ‡	1·28	0·89
Nitrogen evolved on boiling the sludge for two hours with dilute (0·5 per cent.) potash solution	0·13 (May 21st.)	0·03 (May 20th.)

At Chorley the cake is sold for about 10d. to 1s. per ton, but at Dorking it is given away.

The calculated value of those two sludges in the form of pressed cake (50 per cent. moisture), as judged by their manurial constituents alone, is about 6s. to 7s. per ton, but, as experience shows, the market value is less.

Cost of Pressing Sludge.

240. In the majority of the cases cited in the table it has been impossible to ascertain the actual percentage of water in the wet sludge dealt with and in the pressed cake produced. We think, however, that it may be taken broadly that wet sludge contains on the average from 90 to 95 per cent. of water, and pressed cake about 55 per cent. of water. Upon this basis, and dividing our examples into two groups, we estimate the cost of pressing sludge as follows :—

Group I.

In this group we include towns having a population of about 30,000 and upwards, where the preliminary treatment consists either in chemical precipitation followed by sedimentation or in simple sedimentation, and where the sewage does not contain manufacturing waste of a kind likely to necessitate the addition of an unusual quantity of lime to the sludge before pressing.

If the sludge derived from precipitation or sedimentation tanks in these circumstances were to be pressed, it would require the addition of about 2 to 4 per cent. of lime, calculated on the pressed cake produced ; and the cost of pressing, including lime, fuel, labour, press cloths, renewals and repairs, but excluding interest and sinking fund, would amount to from 2s. to 2s. 6d. per ton of pressed cake (55 per cent. water). This would be equivalent to from 5·3d. to 6·6d. per ton of wet sludge, containing 90 per cent. of water.

The interest and sinking fund charges, as given in the table, vary from 4½d. to 1s. 1d. per ton of pressed cake produced, or an average of 9d. per ton of pressed cake. This would be equivalent to 2d. per ton of wet sludge containing 90 per cent. of water. On this basis the *total* cost of pressing, including lime, fuel, labour, press-cloths, renewals and repairs, and also interest and sinking fund, would amount to from 2s. 9d. to 3s. 3d. per ton of pressed cake produced (55 per cent. water), or from 7·3d. to 8·66d. per ton of wet sludge, containing 90 per cent. of water.

Assuming that the pressed cake could be disposed of to farmers without further cost at a price of 6d. per ton, the total cost of sludge disposal at such places would be approximately from 6d. to 7·3d. per ton of wet sludge, including interest and sinking fund charges.

* These oxides will contain the phosphoric acid and possibly a very little of the lime.
† The lime was only precipitated once ; it will contain traces of magnesia.
‡ The figures for phosphoric acid and for total nitrogen are the mean of two closely agreeing estimations.

Group II.

In this group we include towns having a population under 30,000 and also places where 5 to 20 per cent. of lime (calculated on the pressed cake) has to be added to the sludge before pressing, either because the sewage contains much grease, or because septic tank sludge has to be dealt with.

At such places the cost of pressing, including lime, fuel, labour, press-cloths, renewals and repairs, but excluding interest and sinking fund, would probably vary from 3s. to 5s. per ton of pressed cake (55 per cent. water), or from 8d. to 1s. 1½d. per ton of wet sludge containing 90 per cent. of water.

The cost of pressing, including lime, fuel, labour, press-cloths, renewals and repairs, and also interest and sinking fund, at such places would be from 3s. 9d. to 5s. 9d. per ton of pressed cake (55 per cent. water), or from 10d. to 1s. 3½d. per ton of wet sludge containing 90 per cent. of water.

Assuming that the pressed cake could be disposed of without further cost at a price of about 6d. per ton, the net cost of sludge disposal at these places would be from 8·66d. to 1s. 2d. per ton of wet sludge, including loan charges.

From these figures it will be seen that, in the case of large towns, the cost of the disposal of sludge by pressing is about the same as the cost of depositing it at sea. For small towns or for places where septic tank sludge has to be disposed of, the cost is considerably greater. In all cases the cost turns very much upon whether there is a ready sale for the pressed cake, and this is dependent upon having facilities for carting or sending by rail to outlying districts. The pressed cake is worth much more than 6d. per ton, judged by its manurial constituents ; the reason that it fetches such a low price is the relatively high cost of carriage upon a mixture containing of necessity a large proportion of water, grit, and carbonaceous matter.

Shallow Burial of Sludge in the Ground.

241. This plan of sludge disposal consists in mixing the wet sludge from precipitation, settlement, or septic tanks as rapidly and as thoroughly as possible with surface soil. It is usually carried out in the following manner : Small V-shaped trenches, about 2 feet wide at the top and (excluding banking above the surface of the soil) about 1 foot deep, of sufficient capacity to hold the quantity of wet sludge to be disposed of, are cut, if possible, a month or even two months before they are likely to be required, in order to dry and disintegrate the soil. The wet sludge is then run into the trenches and immediately covered over by shovelling in the earth of the banks. The area thus treated is allowed to remain untouched until it is fairly dry, after which it is ploughed and either set aside for cropping or used again for more sludge.

This plan is not widely followed at present, excepting at sewage farms, but it has lately been worked with considerable success by Mr. J. D. Watson, at Birmingham, Mr. C. G. Mason, at Guildford, and Dr. G. J. Fowler, at Withington, in conjunction with artificial filters. By this plan the sludge is cheaply and effectively disposed of, but in wet weather the trenches, both empty and full, require a long time to dry, and, where an offensive sludge has to be dealt with, local nuisance from smell may easily arise.

At Birmingham, where the septic tank sludge has very little smell, little or no nuisance arises, notwithstanding the enormous quantities dealt with ; but at Guildford, owing to the presence of brewery waste in the sewage, there is considerable smell from the trenches. We may point out, however, that strongly smelling sludge can be to a large extent deodorised by the addition of a moderate quantity of lime, and for this reason, though we have no practical experience of the plan, we think that at those places where an offensive sludge had to be dealt with, serious nuisance could be avoided without great cost. At small or medium-sized works, where septic tanks are in use and are cleaned out, say, once every six months, it appears to us that it would be quite practicable to add sufficient lime to the sludge to deodorise it, *before conducting it to the trenches.* This method of disposal would be peculiarly suitable for the treatment of the sludge which is removed from septic tanks at fairly long intervals of time, for in that case a period of dry weather could be selected for the trenching operations.

Area of Land Required.

242. With regard to the kind of land and the area required for the annual disposal of 1,000 tons of wet sludge (90 to 95 per cent. of water), we may quote some particulars which have been given to us.

Mr. J. D. Watson writes (April, 1907) :—

"I cannot differentiate between one kind of land and another, since we have in "the valley of the Tame a great variety of soil. . . . Even in one field we have "occasionally considerable areas of very close marl and equally great areas of "fairly porous gravelly marl. The figure which I give, therefore, is one which "embraces various kinds of soil, but as it is the result of an average taken over "three years, I think it may be assumed to be fairly accurate as representing "*medium quality* of land."

The following table shows the amount of wet sludge dealt with at Birmingham and the area of land used in the form of trenches :—

Year.	Tons of wet sludge dealt with by trenching.	Area of trenches in square yards.	Area of trenches in square yards per 1,000 tons of wet sludge.
1903–4	208,350	265,870	1,276
1904–5	239,203	248,132	1,038
1905–6	109,255	74,167	680
1906–7	104,780	82,747	788

"Climatic conditions have also a considerable bearing upon this question. "In dry weather more sludge can be got rid of on the same area of land than "in wet weather. Methods of working have also a good deal to do with the "results obtained. For instance, where possible it is advisable to cut the trenches "a month or two in advance of their being required, in order to dry the land as "thoroughly as possible. . . .

"Speaking generally, I should say that a quarter of an acre of medium quality "land, worked under usual conditions in this country, is amply sufficient to deal "with 1,000 tons of wet sludge (90 per cent. to 95 per cent. water) per annum."

Mr. C. G. Mason writes (April, 1907) :—

"During 1906, 18,720 tons of liquid sludge were applied to nine acres of "land at Guildford. In the winter months one acre is sufficient to deal with "approximately 2,000 tons, and in the summer months nearly twice that "quantity can be dealt with on the same area of land. The land available for "sludge purposes at Guildford may be described as excellent, consisting as it does "of a light sandy loam, overlying a bed of sand to the depth of 6 feet, with "the water level from 3 to 6 feet below the surface, according to season."

Mr. Mason says that he has not had any experience in dealing with liquid sludge upon unsuitable land, but from general experience he estimates the areas required annually for the disposal of 1,000 tons of wet sludge to be as follows :—

Good land - - - - - - - - - - - - - - ½ acre.
Medium land - - - - - - - - - - - - - 1 „
Bad land - - - - - - - - - - - - - - 2 acres.

"The plan of trenching has certainly been very successful at Guildford, and has "saved the Corporation a large sum yearly from its inception, but I should not care "to make an experiment with wet stiff clay land, an absorbent sub-soil being to "my way of thinking an essential necessity for trenching the precipitated matter "from sewage tanks."

As regards the Withington Sewage Works of the Manchester City Corporation, where the same plan of sludge disposal has been adopted, Dr. G. J. Fowler writes (January, 1908) as follows :—

"The soil at Withington may be described as a sandy loam with a water-logged "subsoil. I should certainly class it as 'medium' soil. For the annual disposal "of 1,000 tons of wet sludge I am of opinion that two acres of such soil should "be provided, though the more soil you have at your disposal the better. Some-

"thing will here depend upon the character of the sludge. The Withington sludge "itself contains a good proportion of sand (77 per cent. SiO_2; 1·76 per cent. "Al_2O_3); a sludge containing a larger percentage of clay, *e.g.*, Davyhulme sludge "(44·3 per cent. SiO_2; 20·85 per cent. Al_2O_3), might require a greater area of "such land.

"Even with the best sandy soil I should recommend, if possible, one acre per "1,000 tons of wet sludge, if it is to be dealt with to the best advantage.

"I am very doubtful whether it is possible to dispose of sludge on clay land, "without some provision of shallow lagoons artificially drained, *e.g.*, by banks of "clinker at frequent intervals.

"Some addition of lime is advisable in all cases where this has not been added "in the course of chemical treatment, either to neutralise the acid produced by "the decomposition of fats or the sulphuric acid produced by the oxidation of "sulphides in sludge from septic tanks."

Allowing ample margin for contingencies, cropping and bad weather, we should from these figures recommend the provision of the following areas of land for the yearly disposal of 1,000 tons of wet sludge (90 to 95 per cent. water):—

Good or fairly good soil	1 acre.
Medium soil	2 acres.
Stiff clay soil,—at least	3 „

Care would have to be taken, as Mr. Watson suggests, to prepare the trenches beforehand, so that the soil might be as dry as possible, and also to remove the sludge from septic tanks in the dry season of the year.

It would be important, moreover, in calculating the amount of sludge likely to be produced at a given place, to include storm water sludge, especially if * stand-by tanks were used for the treatment of the storm water. Tanks of this kind would have to be frequently sludged, and consequently special areas of trenches would be required.

At those places where continuous filters of coarse material were adopted, it would also be necessary to provide for the disposal of the sludge settled out from the effluent.

It must not be forgotten that the disposal of sludge upon land is temporarily interfered with by snow and frost.

Cost.

243. As regards the cost of sludge disposal by burial in the ground, the following particulars relating to Birmingham, Guildford, and Withington have been supplied to us. In all three cases the cost is taken as beginning after the sludge has left the sedimentation tank (*i.e.*, the actual sludging of a tank is not included), and as ending when the trenches are filled in with earth.

BIRMINGHAM.

TOTAL COST OF CONVEYING SLUDGE TO THE LAND AND DEPOSITING IT IN TRENCHES CUT FOR THE PURPOSE.

	Year 1905.	Year 1906.	First 11 months of 1907.
Working expenses of steam plant and attendance:	£. s. d.	£. s. d.	£ s. d.
Engineers and Stokers	65 16 2	70 4 6	76 3 9
Oil, waste, valves, etc.	100 0 0	106 0 0	92 0 0
Coal	83 16 3	89 8 9	77 12 6
Digging trenches, covering sludge, filling in trenches, etc.	719 18 2	644 6 9	516 9 0
Total working cost	969 10 7	910 0 0	762 5 3
Interest on Capital Outlay at 5 per cent., viz., Pump House, Sludge Main, etc.	220 0 0	213 0 0	130 0 0
Rent of land	23 0 0	22 0 0	13 0 0
Total cost, including interest on capital	£1,212 10 7	£1,145 0 0	£905 5 3
Total amount of wet sludge dealt with (90 per cent. to 95 per cent. water)	Tons. 84,890	Tons. 61,996	Tons. 48,872

* *See* section dealing with treatment of Storm Water Sewage, page 204.

At Birmingham the total cost of this method of sludge disposal, including labour, pumping, fuel, interest and sinking fund and rent of land, was therefore approximately **4·0**d. per ton of wet sludge containing from 90 to 95 per cent. of water.

Guildford.

Total cost of conveying the sludge to the land and depositing it in trenches cut for the purpose. The figures refer to the year 1905–6.

	£	s.	d.
Two men employed continuously for regulating and covering in the sludge	101	8	0
One man 3 days per week attending to steam boiler and sludge pump	31	4	0
Firewood for boiler (4 loads @ £1)	4	0	0
Disinfectants	20	0	0
30 tons of fuel for generating steam for pumping sludge	36	0	0
Renewals and sundries	2	8	0
Annual working cost	195	0	0
Add interest and sinking fund for 17 acres of land	252	15	3
	447	15	3

The total quantity of liquid sludge dealt with during the year was 18,720 tons. The cost at Guildford was thus **5·2***d.* per ton of wet sludge, containing from 90 to 95 per cent. of water.

Withington.

The following statement relative to the cost of trenching at Withington has been given to us by Dr. Fowler (January, 1908):—

"The cost of excavating a measured trench, capable of holding 1 cubic yard of "sludge, has been found by the manager of the Withington Works, Mr. C. H. Ball, "to be 1·3d. This low cost is due to the fact that the soil thrown up on either side "of the excavation practically doubles the holding capacity.

"Taking the average cost for the whole year per ton of wet sludge for cutting "and filling trenches, it comes to 2·4d. and the total cost for sludge disposal works "out at about 5·5d. This is exclusive of the rent of land, which would bring the "total up to about **7·0**d., if only so much land is charged for as is absolutely "necessary."

The population draining to the Withington Works is approximately 59,000. The total annual production of wet sludge is something like 14,000 tons.

Lagooning or Air Drying.

244. A lagoon in connection with sludge disposal may be described as an earth tank, from 1 to 6 feet deep, constructed by excavation and banking, or banking alone, with a bottom layer composed of clinker or some such material, in which are laid one or two drains. Occasionally the whole enclosure is constructed of clinker, the banking being made with an easy slope, formed naturally by the fall of the clinker.

Lagooning consists simply in filling such a tank with wet sludge, by gravitation or by pumping, and allowing it to remain there until, partly by evaporation and partly by draining, the sludge becomes dry enough to be removed by spade. When the sludge reaches this state, it is usually wheeled out of the lagoon and dumped on waste land.

There is in our opinion very little to be said for the lagooning of sludge. Once in the lagoon the sludge may take from 2 to 6 months to dry, according to the weather, and during the greater part of this time smell may be said to arise from it. Further, when the sludge is dry enough to be removed, it has still to be disposed of, and being usually moist and closely bound together, it is not readily taken by farmers. The time required by the sludge to dry, however, depends to a great extent upon the depth and the draining of the lagoon. At Darwen, where a large quantity of lime is added to the sludge, and where this mixture is given further settlement in special tanks, the lagoons are only filled to a depth of about 1 foot. As the result of this whole procedure, the

sludge is usually just spadeable in 2 or 3 days—a very short space of time. It is then given away to farmers, the Corporation filling the carts free of charge. At Accrington the lagooned sludge, when dry enough to be spadeable (this takes from 2 to 3 months in dry weather, while in wet weather it may require about 6 months), is sent up the steep side of the quarry in which the works are situated, by means of a truckway, and deposited in canal barges, to be taken to the more purely agricultural districts of West Lancashire. The barge owners pay, on the average, about £2 10s. per barge load of 45 tons. The barges are loaded by the Joint Sewerage Board, the average cost of filling a boat from the works being about 25s.

At Leeds lagooned sludge has gradually accumulated during the past ten years, only a few thousand tons per annum having been disposed of to farmers. We are, however, informed by Mr. G. A. Hart that, as the result of practical advertisement, arrangements have now been made for reducing those accumulations, the sludge being sent by rail or canal to the agricultural districts around Leeds. The loading costs the Corporation 1s. 2d. per ton of sludge (60 per cent. moisture), the farmers who receive it paying the carriage, which amounts to about 1s. 6d. per ton. During the past 7 months 6,000 tons have been disposed of in this way.

It is possible to lessen very greatly the smell from a sludge lagoon by covering the surface of the sludge with soil. This can only be done, however, after the sludge has been in the lagoon sufficiently long to allow of its surface drying into a cake. The plan, moreover, is one which might result in serious danger to workmen or children, especially if the lagoons were deep.

Covering Land with Sludge.

245. This plan consists in simply flooding an area of flat land, which has previously been ploughed, with wet sludge to a depth of 3 or 4 inches. In a few days the liquid portion of the sludge drains away, leaving a layer of sludge which cracks and curls up as it dries. The only examples of the method that we are acquainted with are at Birmingham and Bolton. At Birmingham Mr. J. D. Watson has carried out the plan with success. In his evidence he stated :—

> " If the sludge has been subjected to digestion in septic tanks for a sufficiently " long period, it loses its characteristic pungent and offensive odour. It may either " be pumped into trenches or even put on the surface of land and exposed to the " air until dry, without giving rise to smell ; when thus treated it rapidly settles " down in bulk, and as it dries the surface cracks up. In the course of a few " months it assumes the appearance of a rich black soil."

Watson, 25,034

At Bolton a somewhat similar plan is adopted for the disposal of part of the precipitation sludge from the Hacken sewage works. In this case the land is first ploughed and the sludge is allowed to spread over it, the flow being equalised as much as possible by means of cross grips cut through the furrows. Another plan which is adopted, when possible, is to drill the soil (as for mangolds) and then run the sludge along the bottom of the drills. When the sludge is dry, it is covered over by ploughing or splitting the drills and a crop is taken.

The land treated in this way at Bolton is either sandy clay loam or sandy gravel.

Mr. Ashton, the Manager of the Bolton works, estimates the area of land required for the annual disposal of 1,000 tons of sludge containing 90 per cent. of water as follows :—

(1) Good, or fairly good soil - - - - - - - $\frac{3}{4}$ of an acre.
(2) Medium soil such as sandy loam - - - - - 1 acre.
(3) Heavy soil - - - - - - - - - - 2 acres.

The plan would be quite unsuited for strongly smelling sludge, unless the land used for the purpose were far removed from houses or public roads, or unless the sludge were deodorised in the first instance by the addition of lime or some other suitable substance.

Sludges which give rise to little or no smell are very exceptional. The Birmingham septic tank sludge is comparatively free from smell, but the majority of septic tank sludges from domestic sewage, even when they have remained for a long period of time in the tank, are very far from odourless. We have made no observations at Bolton, but the sewage there contains much manufacturing waste, which may possibly keep down smell.

Cost.

Birmingham.

246. Two sets of figures have been given to us by Mr. Watson, viz., the cost of disposing of the sludge from the Saltley septic tanks, and the cost of disposing of the sludge from the Dortmund or silt tanks at Minworth, these latter being used for the further settlement of the septic tank liquor before filtration. In the first case the sludge is pumped, but in the second no pumping is necessary. In both cases it is septic tank sludge that is dealt with.

Total Cost of Conveying the Septic Tank Sludge from Saltley to the Land and Depositing it.

Working expenses of steam plant and attendance.	Year 1905.	Year 1906.	First 11 Months of 1907.
	£ s. d.	£ s. d.	£ s. d.
Engineers and Stokers	33 13 9	26 10 10	48 11 8
Oil, waste, valves, etc.	44 0 0	34 13 4	58 13 4
Coal	37 2 6	29 5 0	49 10 0
Distribution of sludge over land	45 13 3	50 7 4	42 12 1
Total working cost	160 9 6	140 16 6	199 7 1
Interest at 5% on Capital outlay—viz., Pump House, Sludge Main, etc.	130 0 0	137 0 0	191 0 0
Rent of land	13 0 0	16 0 0	19 0 0
Total cost, including Interest on Capital	£303 9 6	£293 16 6	£409 7 1
Total amount of wet sludge dealt with (90% to 95% water)	50,365 tons	42,278 tons	71,265 tons

The cost of this method of disposal was thus **1·47**d. per ton of wet sludge, containing from 90 to 95 per cent. of water.

Total Cost of Conveying Septic Sludge from Minworth and Depositing it on the Land.

	Year 1905.	Year 1906.	First 11 months of 1907.
	£ s. d.	£ s. d.	£ s. d.
Attendance to Silt Tanks	6 10 0	14 5 3	18 2 1
Distribution and digging into land	16 15 0	37 14 9	44 1 5
Total working cost	23 5 0	52 0 0	62 3 6
Interest on Capital Outlay, viz., Silt Main	57 10 0	57 10 0	57 10 0
Rent of Land	9 0 0	20 0 0	13 5 10
Total cost, including Interest on Capital	£89 15 0	£129 10 0	£132 19 4
Total amount of wet sludge dealt with (90% water)	6,226 tons.	21,605 tons.	36,299 tons.

The cost of disposal in this case was therefore **1·32**d. per ton of wet sludge containing 90 per cent.* of water.

Bolton.

247. In the case of Bolton the total cost of the plan for the year ending November 30th, 1907, when 25,000 tons of sludge containing 90 per cent. of water were dealt with on 25 acres, was approximately 5·04d. per ton.

* The above figure of 90 per cent. water in the sludge was in this case actually determined.

It should be noted, however, that the sludge gravitates to the land from the precipitation works at Hacken—a distance of some miles—through a conduit which is used chiefly for the conveyance of tank liquor to the land for filtration. No portion of the interest and sinking fund charges on this conduit are included in the above cost for sludge disposal.

Burning of Sludge.

248. There have been many attempts to dispose of sewage sludge by burning it either alone or mixed with house refuse, coal, oil, or resin. Most of these have failed, owing either to the heavy cost of drying the sludge before burning, or to the fact that the attempt was made on wet sludge containing something like 90 per cent. of water. It is practicable, however, to burn pressed cake. At Ealing (Southern Works) Mr. Charles Jones has for some years disposed of pressed sludge (containing about 60 per cent. of water) in this way. At those works the pressed cake is dropped from the presses into trucks, which are then conveyed by a hydraulic lift to the destructor furnaces. There it is mixed with dry house refuse, in the proportion of about 1½ or 2 parts of dry refuse to 1 of pressed cake, and burnt. The steam generated is utilised for lime mixing, for sludge-pressing and the manufacture of artificial paving slabs, and for pumping a portion of the sewage. We have not been able to ascertain the cost of the process, but about 2,500 to 3,000 tons of pressed cake have been disposed of per annum in this way during the years 1905, 1906, and 1907.

249. Reference may also be made to the evidence given by Mr. K. F. Campbell of Huddersfield in regard to an *experimental* plant. At that place a portion of the sludge obtained by means of chemical precipitation is pressed and, having been tipped into feeding bins at the back of the furnaces, is there mixed with 20 per cent. of coke breeze and fed by hand into the furnaces. The burning plant consists of a two-cell Horsfall destructor, each cell having a grate area of 30 square feet, with a drying hearth at the back; the cells are placed side by side and each is fitted with a patent Silent Steam Blower. The furnaces are so arranged that all the fumes given off by the pressed cake, in drying, have to pass over the hottest part of the fire before they escape to the chimney. Campbell, 21,787–802.

Mr. Campbell's original intention was to burn the pressed sludge mixed with an equal quantity of town refuse, but owing to the difficulty in getting the refuse to the sewage works, this was abandoned and coke breeze was substituted. Occasionally a little engine slack has been used, mixed with the coke breeze, but this is not a regular occurrence. During the year 1907 a trial has been made with gas-works clinker containing a fair proportion of coke and combustible matter. The following particulars relating to the years 1901–6, inclusive, have been kindly given to us by Mr. Campbell:—

Year ending:—	Sludge Cake burnt in destructors.		Coke Breeze used.		Coal used.		Gasworks clinker used.	
	TONS.	CWT.	TONS.	CWT.	TONS.	CWT.	TONS	CWT.
March, 1901	5,421	14	911	1	121	0	101	16
,, 1902	34	8	7	10	—		—	
,, 1903	136	0	27	9	—		—	
,, 1904	220	14	42	11	—		—	
,, 1905	61	3	7	8	2	17	—	
,, 1906	74	9	12	9	—		—	
Total	5,948	8	1,008	8	123	17	101	16

The proportion of fuel added to the pressed cake was thus about 1 to 5.

The clinker obtained from the burnt sludge is rather too friable for use in sewage filters, but Mr. Campbell states that when it is ground up and mixed with cement or lime it forms an excellent mortar, of which much has been used in the present re-construction of the works.

Cost.

The cost of pressing and burning varies with the price of the materials (lime, coke breeze, etc.). The following are the average costs for each :—

PRESSING.

Cost per ton of Pressed Cake Produced.

	s.	d.
Labour	1	5·3
Lime (13s. 3d. per ton)	–	9·3
Press Cloths	–	3·7
Total	2s.	6·3d.

BURNING.

Cost per ton of Sludge Cake Burnt.

	s.	d.
Coke Breeze (7s. 6d. per ton)	1	6·4
Stokers	–	7·2
Mixers	–	5·3
Total	2s.	6·9d.
Total cost of pressing and burning (per ton)	5s.	1·2d.

These figures do not include cost of power for pressing, on the one hand, but, on the other, no allowance has been made for fuel value or for clinker produced.

It will be seen that the above process, as carried out on a large experimental scale at Huddersfield, is costly, but probably the whole of the final product can be utilised and the sludge is entirely got rid of.

Extraction of Valuable Substances from Sewage Sludge.

250. The chief example of the extraction of a valuable substance from sewage sludge is afforded by Bradford. As is well known, the sewage there contains a considerable quantity of wool-scouring liquor and is consequently of a very greasy nature. For some years experiments having for their object the extraction of the grease have been in progress, and Mr. J. Garfield, the City Engineer, has now been so far successful that the return from the sale of the products more than meets the working expenses of the tank treatment of the sewage,* leaving out of account the charges in respect of principal and interest on loans. The dry weather flow of sewage is approximately 13,000,000 gallons per day, about half being trade waste. Of the trade waste 20 per cent. is wool-scouring liquor, and of this about 90 per cent. is treated by manufacturers for the recovery of grease before being discharged from the premises. The remaining 80 per cent. of trade waste comes from dyers, printers, chemical manufacturers, tar distillers, cloth manufacturers, waste pullers and scourers, yarn finishers, cloth washers, carbonizers, silk manufacturers, tanners, oil distillers, paper manufacturers, size manufacturers, brewers and galvanizers. In all, about 274 traders discharge their waste liquor into the sewers.

The process of treating the sewage at the works is as follows : The sewage is passed through detritus tanks, from which about 10 cubic yards of detritus are removed per day. It is then screened and sulphuric acid is added in such quantity that there is an excess equal to 10 parts of acid (H_2SO_4) per 100 000. The acid sewage is subsequently

* The treatment of the sewage at Bradford does not go beyond precipitation.

passed through settling tanks, used in series, the tank liquor being discharged into the Bradford Beck in a slightly acid condition. The following figures give the average chemical composition of the sewage and the tank liquor :—

	Parts per 100,000.	
	Crude sewage.	Tank liquor.
Suspended matter	84·0	16·0
Solids in solution	181·0	224·0
"Oxygen absorbed" in 4 hours	17·90	11·18
Free ammonia	3·00	1·87
Albuminoid ammonia	2·45	1·80

The sludge is removed from the settling tank into cast iron vats, where a further quantity of sulphuric acid is added and the temperature of the sludge is raised by means of exhaust steam from the boilers to about 100°C. It is then run into steel rams and forced by means of compressed air into the filter presses. The filter presses are heated by steam, and the process of pressing is continued from 12 to 24 hours, hot sludge and steam being alternately admitted to the press. The pressed liquor, which consists of water and fat, is run into special vessels for the separation of the fat, after which the fat is boiled with acid and black oxide of manganese, in order to bring it into a marketable condition.

The amount of wet sludge produced in a year is about 100,000 tons. It contains about 80·15 per cent. of water and 7·43 per cent. of grease, which is equivalent to 37·7 per cent. of grease on the dry solid matter.

The amount of pressed cake produced during the year is about 20,000 tons. This contains about 27 per cent. of water. Part of the pressed cake is used for fuel and is burnt in specially constructed brick furnaces; the fuel value is about 1s. 6d. per ton. Part is sold to farmers at 3s. 6d. per ton on rail at the works. Another portion is disintegrated and sold as manure at 5s. 6d. per ton, whilst 6s. 3d. per ton is obtained for the driest portion of the disintegrated pressed cake.

For the six months ending September 30th, 1907, the total expenditure on the sewage works, exclusive of principal and interest on loans, amounted to £9,960 0s. 3d. and the receipts from the sale of grease, etc., to £11,726 15s.

The following table, which has been given to us by Mr. Garfield, shows the figures in detail. The expenditure includes the salaries of the chemical and clerical staff, and the whole of the costs in connection with the Sewage Disposal Works, except the Chief Engineer's salary, and interest and sinking fund on loans.

Expenditure.	£	s.	d.	Receipts.	£	s.	d.
To Sulphuric Acid, Fuel and Stores	7,250	3	4	By Grease, Manure, etc.	11,726	15	–
To Salaries and Wages	1,907	12	–½				
To Gas	161	11	3				
To Water	90	19	10				
To Insurance and Sundries	122	13	9½				
To Rent, Rates and Taxes	427	–	–				
To Balance	1,766	14	9				
£.	11,726	15	–	£.	11,726	15	–

251. We may also refer to a process of sludge distillation (Watson and Butterfield's Patent Sludge Distilling Process), which was brought to our notice by Mr. George Watson of

the Horsfall Destructor Co., Ltd. The object of this process, an experimental installation of which was inspected by one of our officers on July 6th, 1907, is to recover the nitrogen from the sludge in the form of ammonia, and to utilise at the same time the carbonaceous matter for the purpose of generating heat. The following description of the process has been supplied by Mr. George Watson. It must, of course, be understood that we are not responsible for the claims advanced by Mr. Watson, in regard to the process. We can express no opinion in regard to them.

" The treatment of the sludge as taken from the precipitation tanks involves, on this principle, three " separate processes. Firstly, the removal of a portion of the water by mechanical means; secondly, " the removal of a further portion of the water by drying; and thirdly, the destructive distillation of the " partially dried sludge."

(1) *Pressing.*

" The sludge when taken from the precipitation tanks contains about 90 per cent. of water. The " best method at present in use for getting rid of some of this water is filter-pressing. By this means the " proportion of water in the sludge may be reduced to 50 or 60 per cent.'

" Sludge containing 90 per cent. of water, when pressed until it contains 60 per cent., is reduced to " one-fourth of its original bulk; if pressed until it contains 50 per cent. of water, it is reduced to one- " fifth of its original bulk. The cost of filter-pressing is in one instance as low as 1s. 10d. per ton of " pressed cake, but the average cost at the present time may be put at from 2s. 3d. to 2s. 6d. per ton " of pressed cake containing from 50 to 60 per cent. of water."

(2) *Drying.*

" After the sludge has been filter-pressed, it is necessary to dry it until it contains only 20 to 25 per " cent. of water, before putting it into the retort for distillation. Wherever a sufficiently large space " of ground is available and only a comparatively small quantity of sludge has to be treated, the drying " may be most economically effected by exposing sheds. Where considerations of capital are not deterrent " or where space is limited, the sludge may be dried by passing it through mechanically driven rotary " cylindrical driers, heated by the hot waste gases of combustion, which leave the flues round the distilling " retort after having heated the retort.

" The sludge as it leaves the filter-presses can be readily transported to the driers on band-conveyors. " Filter-pressed sludge containing, say, 60 per cent. of water, when dried until it contains 20 per cent. " of water, is reduced approximately to half its weight and bulk.

" The sludge is now in the form of sufficiently dried cakes to be easily transportable mechanically " by conveyors or elevators to the retort, and suitable for the treatment by destructive distillation at a " high temperature.

" The gases from the interior of the cylindrical drier, before reaching the chimney, may be passed " through a scrubber which recovers any ammonia given off by the sludge during drying operations, " thus effectually preventing any smell which may arise from this source.

" The cost of drying is estimated at 1s. 6d. per ton of dried sludge (containing 20 per cent. of water), " which is equivalent to a cost of 9d. per ton of filter-pressed sludge containing 60 per cent. of water."

(3) *Destructive Distillation.*

" The retort used for the distillation may be of firebrick, but is preferably made of cast iron, and is " oval in section, so as to enable the heat to penetrate readily through the material in the interior.

" The retort is set vertically and is slightly larger in section at the bottom than at the top, so as to " facilitate the downward movement of the sludge cake. The top of the retort is closed air-tight by a " cup and cone arrangement, through which the dried sludge cake is fed at regular intervals. The bottom " of the retort is similarly closed by a cone, which can be operated so as to let out the spent residue from " the distillation, as may be desired. The retort is placed in a brickwork setting and is heated by the " combustion of gas in a combustion chamber and in flues passing around and up its sides, preferably " in a spiral path.

" The volatile products arising from the distillation are taken off towards the top of the retort through " a pipe connected to the side, and the gases are pulled forward and outward by an exhauster which " maintains a pressure inside the retort slightly below the atmospheric pressure.

" After leaving the retort the volatile products of distillation are passed through a condenser and " subsequently through a scrubber, which extracts the moisture, oil, tar and ammonia. The inflammable " gas which now remains is passed into the combustion chamber of the retort and there burnt.

" The heat obtained from the combustion of this gas is sufficient to maintain the retort at the desired " temperature, but an auxiliary source of heat is provided by a gas producer or furnace which is used in " starting the operation.

" The lower part of the retort is maintained at a temperature of 1,500° to 1,800° F.

" Steam is blown into the retort, near the bottom, and in passing through the hot zone in the retort " it reacts on the carbonaceous material of the sludge, and in the presence of the lime, and at the high tem- " perature there existing, the nitrogen in the sludge is liberated and evolved as ammonia.

" The products obtained from the distillation are: (1) Oil; (2) ammonia; (3) combustible gas; " and (4) mineral residue."

(1) *Oil.*

" The oil is run off from the top of the ammoniacal liquor coming from the condenser, by means of an " oil separating tank. The oil thus obtained has not yet been thoroughly examined, but it probably has " a value far higher than that of fuel oil, although this is not necessary for the economical success of the " process.

" The yield of oil depends on the method of distillation, being much greater if a comparatively cool " zone is maintained at the top of the retort. The yield of oil from the sewage of different localities also " varies greatly."

(2) *Ammonia.*

" The ammoniacal liquor from the condenser and scrubbers is treated with sulphuric acid in the ordinary " way and is converted into ammonium sulphate.

" The yield of ammonia varies to some extent with the locality from which the sewage is derived. The " economical disposal of sewage sludge in this way depends on the recovery of the ammonia from the " sludge in sufficient quantity to cover the cost of treatment."

(3) *Gas.*

" The gas is burnt around the retort and provides the heat necessary for the distillation."

(4) *Residue.*

" The spent residue from the retort is freed entirely from any trace of organic matter by its treat- " ment in the retort, and is of a light friable nature and easily reduced to a fine powder. It contains " lime and some phosphates and is in a form very suitable for direct application to land, either alone " or enriched by the addition of concentrated manures. On the other hand it might possibly be used " as a precipitant for the sewage, along with a small proportion of fresh lime. By constantly using the " same material over again, the percentage of phosphate of lime in the material would be so increased " as to make it valuable as a manure. Where too much iron is not present, the residue can be used as " a cement of fair quality.

" The quantity of residue remaining after distillation is about 50 per cent. of the solid material present " in the sludge, or 40 per cent. of the sludge (containing 20 per cent. of water) as charged into the retort. " The percentage of residue varies in different localities according to the amount of surface water run " into the sewers. In some cases a large amount of mineral matter is thus swept into the sewage, which " increases the proportion of inorganic solids in the sludge."

The following figures show the amounts of the different products obtained by this process of distillation. In every case, to avoid confusion, the figures given are calculated per ton of *absolutely dry sludge*—that is, per ton of solid matter in the sludge.

Date.	Locality from which the sludge was obtained.	Oil.	Ammonium Sulphate.	Residue.
October, 1906 -	Bradford - - -	Not measured.	97·7 lbs.	42% (small sample only tested).
„ „ -	Bury - - -	30 gallons.	120 lbs.	47% do.
„ „ -	„ - - -	37 „	124 lbs.	47% do.
„ „ -	Southall - - -	6·2 „	81·7 lbs.	47% do.
April, 1907 - -	Leeds - - -	24 „	103 lbs.	50% do.
October, 1907 -	„ - - -	*Not measured.	109·2 lbs.	50% (one ton distilled in large retort).

* The retort was too hot at the top to yield oil.

Comparison of Cost of Different Methods of Disposal of Sludge.

252. The cost of disposing of sludge depends not merely upon the method adopted, but also, and to a large extent, upon the local circumstances of each place. This must be carefully borne in mind in considering the following table :—

Comparative Cost of the Various Methods of Sludge Disposal, as instanced by the Examples Given.

Method of sludge disposal.	Number of examples.	Maximum and minimum cost of the process, in pence, per ton of sludge containing 90 per cent of water, including interest and sinking fund and all other charges.*	Average cost of process, in pence, per ton of sludge containing 90 per cent of water, including interest and sinking fund and all other charges.
Covering land with sludge - - -	3	Minimum 1·32d. Maximum 2·8d.	say, 2d.
Sea disposal - - - - - - -	6	Minimum 4·1d. Maximum 6·9d.	say, 5d.
Trenching in soil - - - - -	3	Minimum 4·0d. Maximum 7·0d.	say, 5d.
Pressing. Group I. - - - -	10	Minimum 4·8d. Maximum 7·3d *	say, 6d.
Pressing. Group II. - - - -	11	Minimum 7·7d. Maximum 12·6d.*	say, 11·5d.
Pressing and burning - - - -	1 (experimental)	13·3d. (excluding interest and sinking fund.)	say, 18d.†

The cheapest examples of disposing of sludge come under the heading of "covering land with sludge." This is, of course, what would be expected, for little labour is necessary in connection with the plan. The success of the method depends upon having a sufficient area of good, or fairly good, soil in flat formation. On account of smell, the plan would, as a rule, only be suitable where the sewage works were far removed from houses and public roads.

The two cases of an actual profit arising out of the disposal of the sludge, viz., Kingston-on-Thames and Bradford (Yorkshire) are not included in the table.

In the table no credit has been given either for the manurial value of the sludge disposed of by covering land or trenching, or for the fuel value of the sludge and the production of clinker in the "burning" method.

With regard to the burning of sludge, if this process were so modified as to permit of the recovery of the nitrogen of the sludge, its cost would probably be much reduced.

* Owing to the great variations in the actual figures for interest and sinking fund, mainly because of the different dates at which the sewage works were constructed, we have been obliged, in dealing with "Pressing," to take an approximate average figure for this item, viz. 9d. per ton of pressed cake containing 55 per cent. of water, or 2d. per ton of sludge containing 90 per cent. of water.

† This figure is an estimate.

MANURIAL VALUE OF SEWAGE SLUDGE.

253. Opinions in regard to the manurial value of sludge were of so conflicting a character that we thought it advisable to institute some accurate experiments with various sewage sludges.

Through the kindness of the Board of Agriculture and Fisheries, these experiments were carried out at several collegiate centres under their supervision.

The experiments took the form of three series as follows :—

Series 1.—Experiments with mangolds and swedes at five collegiate centres, under the supervision of Dr. W. Somerville.

Series 2.—Experiments with grass at eight collegiate centres under the direction of Professor Middleton, and at Woburn by Dr. J. A. Voelcker.

Series 3.—Pot-culture experiments at Woburn by Dr. J. A. Voelcker.

The reports on these experiments are given in Appendix VIII.

In all three series of experiments the same sewage sludges were used, and in each case the sludge was artificially dried before being sent to the experimental stations. Its carriage would otherwise have presented much difficulty.

The sludges were derived as follows :—

SLUDGE No. 1.—*Composite precipitation sludge produced by the Native Guano Co., Ltd., at Kingston-on-Thames :—*

This sludge consists of the precipitate deposited in continuous flow tanks, as the result of adding alumino-ferric, blood, charcoal and clay (together about 50 grains per gallon) to the Kingston sewage, which is mainly domestic in character, but which contains a small proportion of waste liquors from breweries and a gas works.

Having been pressed into cake and then artificially dried at a temperature of about 75° Centigrade, it was stored under cover for some time previous to sampling.

SLUDGE No. 2.—*Composite precipitation sludge from Dorking, Surrey :—*

This sludge consists of the precipitate deposited in continuous flow tanks as the result of adding lime (10 grains per gallon) and alumino-ferric (5 grains per gallon) to the Dorking sewage, which is almost entirely domestic in character.

It was first pressed into cake and then dried by placing portions of it in thin layers near a boiler. A further quantity of lime, equivalent to about 120 lbs. per ton of pressed cake, was added previous to the pressing.

SLUDGE No. 3.—*Alumino-ferric precipitation sludge from Chorley, Lancashire :—*

This sludge consists of the precipitate deposited in quiescent settling tanks as the result of the addition of alumino-ferric (9 grains per gallon) to the Chorley sewage, which is domestic in character.

Having been pressed and partially dried under cover, it was further dried by placing it in small quantities on either side of a boiler. Previous to the pressing a quantity of lime, equivalent to 1 cwt. per ton of pressed cake, was added to the sludge.

SLUDGE No. 4.—*Composite precipitation sludge from Leeds, prepared by Alton's process :—*

This sludge consists of the precipitate deposited in a continuous flow tank as the result of adding calcium phosphate (4 to 5 grains per gallon) in acid solution and subsequently lime (about 1 grain per gallon) to the Leeds sewage, which is rather dilute and contains a considerable proportion of waste liquors from various manufactories.

The wet sludge was first drained in a lagoon and afterwards dried artificially by placing it near a boiler.

Sludge No. 5.—*Septic tank sludge from Leeds :—*

This sludge consists of the deposit in an open septic tank which had been receiving Leeds sewage for a period of three years. The flow of sewage into the tank during this time was sufficient to fill it once every twenty-four hours. The wet sludge was first drained in a lagoon and afterwards dried artificially by placing it near a boiler.

Sludge No. 6.—*Settled sewage sludge from Leeds :—*

This sludge consists of the deposit settling in the second of a series of continuous flow subsidence tanks used at Leeds for the treatment of the main flow of sewage. The wet sludge was first drained in a lagoon and afterwards dried artificially by placing it near a boiler.

Sludge No. 7.—*Composite precipitation sludge from Glasgow (Dalmarnock), known as " Globe Fertilizer " :—*

This sludge consists of the precipitate deposited in continuous flow tanks as the result of the addition of persulphate of iron (8 grains per gallon) and lime (4 to 5 grains per gallon) to the Glasgow (Dalmarnock) sewage, which contains much manufacturing waste.

The sludge was first pressed and then artificially dried at a temperature of 65° to 75° Centigrade, and finally passed through a pan mill.

The chemical compositions of the sludges used in the experiments are given in the Reports, but we may say here that No. 1 sludge contained the most nitrogen and phosphoric acid, and Nos. 2 and 4 the most lime.

Series 1.

Dr. Somerville's Experiments with Turnips, Mangolds, and Swedes.

254. Table I. gives the names of the five experimental stations where this series of experiments was carried out, together with the nature of the soil and the crop grown.

Table I.

Place.	Nature of Soil.	Crop Grown.
Rothamsted Experimental Station (Mr. G. D. Hall) -	Strong flinty loam overlying chalk.	Mangolds.
Agricultural Department, Cambridge University (Prof. Middleton).	Moderate gritty loam overlying gault.	Mangolds.
Agricultural Department, Leeds University (Prof. Seton).	Strong drift soil overlying the coal measures.	Swedes.
South-Eastern Agricultural College, Wye (Prof. Dunstan).	Strong flinty loam overlying chalk.	Swedes.
Glasgow and West of Scotland College of Agriculture (Prof. Wright).	Strong loam on the carboniferous formation.	Turnips.

The scheme of the experiments was as follows :—

At each station twenty-two plots in duplicate, each $\frac{1}{20}$ of an acre, were selected.

It was decided to use, as far as possible, 40 lbs. of nitrogen and 36 lbs. of phosphoric acid per acre, and 2,072 lbs. of sludge No. 1 were required to supply these amounts. Since the other sludges contained less nitrogen and phosphoric acid than No. 1, 2,072 lbs. did not in their case supply as much as 40 lbs. nitrogen and 36 lbs. phosphoric acid. It was obviously impossible to apply equal quantities of the manurial constituents from all the sludges, while it was also inadvisable to attempt to get over this by the addition of artificial manures. On the first seven duplicate plots an amount equal to 2,072 lbs. per acre of each of the sludges was therefore used. Plots 8*a* and 8*b* received an amount equal to half the above quantity per acre of No. 1 sludge (*i.e.*, 1,036 lbs. per acre), Plots 9*a* and 9*b* received no sludge, and Plots 10*a* and 10*b* received 3,108 lbs. per acre of No. 1 sludge. The other twelve duplicate plots were used for comparative experiments with No. 1 sludge mixed with either sulphate of ammonia, superphosphate, or both, and also for experiments with sulphate of ammonia, superphosphate and fish meal, either together or alone.

The whole of the experimental area received an equal dressing of potash salt, supplying 30 lbs. of potash (K_2O) per acre :—

" The season was somewhat abnormal in character and, on the whole, not very favourable to the action " of manures. From the Midlands northwards the early part of the summer was characterised by great " deficiency of rain, with the result that seed germinated badly and young plants received a check in growth. " At Leeds the root crop on the experimental area was a total failure, so that no figures are available from " this centre.

" At the other centres the yields were fair, being above the average at Cambridge and below the average " at Glasgow."

255. From the results obtained with given weights of nitrogen and phosphoric acid added in the form of artificial manures, Dr. Somerville determines the sensitiveness of the soil to manurial treatment, showing :—

(1) That nitrogen alone (sulphate of ammonia), unsupported by phosphates, produced no positive result at any of the centres, so far as turnips and swedes are concerned. On the other hand, with mangolds at Rothamsted and Cambridge a large increase was obtained.

(2) That the use of 20 lbs. of nitrogen (sulphate of ammonia) per acre, together with phosphoric acid in the form of superphosphate, produced a marked increase of crop in every case.

(3) That 18 lbs. per acre of phosphoric aid (as superphosphate) alone produced no increase of crop, while, with the exception of Wye, 36 lbs. of phosphoric acid per acre produced an increase at all the centres.

Comparing the results obtained with sludge No. 1 alone and mixed with either superphosphate or sulphate of ammonia, he shows :—

(1) That the phosphate of the sludge is less active than the phosphate in the superphosphate, because the addition of a further quantity of phosphoric acid in the form of superphosphate produced a greater relative effect in the former case than the latter.

(2) That there are similar indications with regard to the nitrogen of the sludge.

From the direct comparison of the effects of equal weights of nitrogen (20 lbs. and 40 lbs. respectively) and phosphoric acid (18 lbs. and 36 lbs.) derived from sludge No. 1 and from sulphate of ammonia with super-phosphate and with fish meal, Dr. Somerville shows that the sludge-grown crop is in nearly every case considerably inferior in weight to the crop grown with artificial manure. In several cases the sludge-grown crop was smaller than the crop grown on the unmanured plot (No. 9).

In comparing the results obtained with all seven sludges, he says :—

" Taking the average of all the centres and the average of the seven plots that got 2,072 lb. per acre of " sludge, we find that the yield works out at 19 tons 7 cwt. per acre, which is practically a $\frac{1}{2}$ ton less than " the average yield on the unmanured plot (No. 9). Or, looked at from another point of view, it will be " seen that the highest yield of any of the sludges is that of No. 2 (Dorking) on Plot 6, where it amounts " to 20 tons $5\frac{3}{4}$ cwt., a figure that is lower than the average yield on any of the plots receiving artificial " manure."

Dr. Somerville's general conclusion is as follows :—

" So far as these experiments go, they show that in the season of 1905 none of the sludges experi- " mented with produced any consistent manurial effect on the growth of turnips, swedes, or mangolds. Al- " though the season was not a good one for the growth of the root crops, it permitted artificial manures to " exert a considerable influence upon the yield of this crop. We would, therefore, appear to be justified in " drawing the conclusion that the nitrogen and phosphoric acid of sludge are in a much less available form " than the same substances in sulphate of ammonia, superphosphate, and fish meal."

In view of the difficulty of the whole subject, it was thought desirable to continue the experiments for another year, this time with hay as the crop to be grown.

Series 2.

(a) *Experiments with Sewage Sludge upon Hay, under the Supervision of Mr. T. H. Middleton.*

256. The general scheme of this series of experiments was similar to that of Series 1, except that eight centres were chosen and the crop grown was hay.

At most of the centres twenty-five plots of $\frac{1}{20}$ of an acre each (not in duplicate) were used, but at Cambridge there were thirty-four plots.

The first seven plots received equal weights of the seven sludges; Plots 8, 9, and 11 different weights of Sludge No. 1; Plots 10 and 23 were unmanured; Plots 12, 13 and 14 received No. 1 Sludge with various artificial manures; Plots 15 to 22 combinations of artificial manures alone, while Plots 24 and 25 received lime alone. The artificial manures employed in this instance were basic slag and sulphate of ammonia.

The sludges were the same as in Series 1, but made a year later: as will be seen from the chemical analyses, their composition varies slightly. Sludge No. 1 again contained the most nitrogen and phosphoric aid, and Nos. 2 and 4 the most lime.

Table II. gives the names of the centres at which the experiments were carried out with the nature of the soil and the condition of the meadow land.

TABLE II.

Centre.	Nature of Soil.	Condition of Meadow Land.
(1) The North of Scotland College of Agriculture, Aberdeen.	Poor, wet clay.	Field had been in grass for six or seven years, but was in extremely poor condition.
(2) The West of Scotland College of Agriculture, Glasgow.	Heavy clay.	Grass in its first year.
(3) The Armstrong College, Newcastle-on-Tyne.	Clay loam.	Field had been in grass for about thirty years.
(4) The University, Leeds.	Medium loam.	Old meadow land.
(5) The University College of North Wales, Bangor.	Gravelly soil.	Old meadow land.
(6) The Agricultural Department, Cambridge University.	Medium, but sticky loam.	Pasture of fifteen to twenty years' standing.
(7) The Rothamsted Experimental Station, Harpenden, Herts.	Heavy clay loam.	Old meadow land.
(8) The South-Eastern Agricultural College, Wye, Kent.	Somewhat stiff loam overlying chalk.	Pasture of some years' standing.

257. Mr. Middleton's report should be referred to, but we may say that the broad results show that at the northern stations, where the wet summer was favourable to slow-acting manures, the application of sludge seems to have been useful.

In the South of England, where the hay is cut much earlier, the sludges produced no results whatever.

Speaking generally, the two sludges containing the most lime, viz., Nos. 2 and 4, gave the best results among the sludge grown crops.

In a general survey of these experiments and the experiments of Series 1, Mr. Middleton says:—

"The figures obtained in this experiment and in the corresponding experiments made last year are not "of a satisfactory character, and do not permit of any conclusions as to the relative money values of sludge "and artificial manures.

"The only definite conclusion which may be stated is that, for root crops and grass, the action of the "nitrogenous and phosphatic constituents of sludge is very slow, as compared with the effect produced by "nitrogen and phosphates supplied in ordinary artificial manures.

"For such crops as mangolds, potatoes and swedes, which have a short period of growth and require "quick acting manures, sewage sludges would not appear to be well adapted, and if they are employed they "should be applied in tons rather than in hundredweights per acre.

"On the other hand, although these experiments do not supply the evidence, it seems likely that sludge "used in proper quantities would form a good dressing for the slow growing plants of many permanent pastures "and meadows.

"Sludge is unlikely to give satisfaction on the very poor clay-soil pastures which are so much benefited "by basic slag, but for old grass land of moderate quality it should prove useful."

It is instructive to note the indication that sludges produced by precipitation with lime are probably more valuable as manures than sludges derived from precipitation with salts of alumina or iron. As is well known, phosphate of lime is much more readily assimilated by plants than phosphate of iron or alumina.

This series of experiments upon hay is being continued at some of the stations for another year without any fresh application of sludge.

(b) *Experiments with Sewage Sludge on Grass Land at Woburn, by Dr. J. A. Voelcker.*

258. These experiments were on much the same lines as those carried out under Mr. Middleton.

Eleven plots of $\frac{1}{10}$ of an acre were marked out in a field that had been long in grass, but which could only be described as of moderate quality. The field is on the junction of the Lower Greensand with the Oxford Clay, the soil partaking of the character of both formations.

The first seven plots were respectively dressed with each of the seven sludges in quantity sufficient to supply 40 lb. of nitrogen per acre, Plots 8, 10 and 11 received ordinary mixtures of artificial manures, and Plot 9 was left unmanured. Plots 8, 10 and 11 also received a dressing of lime. Exactly the same sludges were used as in Series 2 (*a*).

"All the sludges, with the exception of Nos. 2 and 4 (which were rather 'sticky' in nature, and would "in practice be rather difficult to sow), were in fair condition and could be easily manipulated. Very little "rain fell during the months of February and March, the recorded rainfall at Woburn being only 0·99 inch "for February and 0·83 inch for March. In April, however, there was much more, and on April 12th 0·44 "inch of rain fell, this being the first real washing which the manurial applications received. This fact "and the absence of warmth by which the season was marked no doubt militated much against the sludges "increasing any decided benefit, and it is, indeed, very probable that the results now recorded cannot fairly "be taken as a guide to the real or relative values of the sludges. In all experiments conducted on grass land "it is unfair, and often misleading, to take the results of a single year as conclusive, and especially is this the "case when an abnormal season like that of 1907 enters into the calculation."

When the hay was cut on July 15th it was found that there was little difference in weight of crop from any of the first six plots, the produce ranging from about 2 tons per acre (Plot 1) to about 2 tons 4 cwt. per acre (Plot 4). Plot 7, receiving Sludge No. 7; Plot 8, receiving superphosphate, 3 cwt. per acre and lime 5 cwt.; and Plot 9, which received no manure, gave from about 2 tons 5 cwt. (Plot 8) to about 2 tons 7 cwt. (Plot 7) of hay.

Plot 10 (superphosphate 3 cwt., lime 5 cwt., sulphate of ammonia $\frac{3}{4}$ cwt.) gave about 2 tons 8 cwt., and Plot 11 (sulphate of ammonia $1\frac{1}{2}$ cwt.), 3 tons 3 cwt.

259. Summarising these results Dr. Voelcker says :—

"There is, I think, little more to be said than that, for all practical purposes, the sludges did not 'tell' "during this season, but that they require longer time to show their influence, and that the only clear benefit "was to be traced to the more quickly acting (because more soluble) material, sulphate of ammonia. That "even this increase will, in the end, be a beneficial one, is by no means certain, for the mere 'flushing' of a "grass field to give an extra cut for hay by no means results necessarily in the improvement of the pasture "permanently. Here, again, continuation of the experiment for other years is called for."

Series 3.

Pot Culture Experiments at Woburn by Dr. J. A. Voelcker (1907).

260. In addition to the foregoing experiments with grass, Dr. Voelcker also carried out a detailed series of experiments with wheat at the Woburn Pot Culture Station, experiments which involved much care and trouble.

The same seven sludges were used.

The experiments were divided into three groups :—

(1) A comparison of the manurial effect, on the wheat crop, of one kind of sewage sludge as against another, when these were respectively applied in quantities calculated to supply 40 lbs. of nitrogen per acre.

(2) A comparison of the effect of each individual sludge with that of an artificial dressing composed of superphosphate, rape dust and lime, calculated to supply the same amounts of phosphoric acid, nitrogen and lime as did the corresponding sludge.

(3) A comparison of the cost of increase of crop obtained by the addition of sludge and by artificial manures of known cost. In this experiment the sludges were used in equal weights (2 tons per acre) and compared with dressings of artificial manures such as a farmer would be likely to use.

Every experiment was carried out in triplicate, the plan being to grow the wheat in pots of certain size filled with soil of known composition. In filling the pot the last fifth of the soil was thoroughly incorporated with the sludge or artificial manure used in the experiment. The pots held 40 and 32 lbs. of soil. Control experiments for each size of pot were also made at the same time.

When the pots were all filled, on December 5th, 1906, they were each sown with twelve seeds of wheat, the young plants being thinned out to six in each pot on April 11th, 1907. As regards the plants removed at the time Dr. Voelcker says :—

"... a comparison of the rootlets of the plants then removed showed very little difference between "one sludge and another, but in each case the artificial equivalents had given the larger and stronger root "growth."

"About April 22nd the first change in appearance showed itself, the sludge grown plants being then "slightly in advance of the untreated ('control') ones, and the flag presenting a darker colour. The plants "of Sludge 1 and 4 were the best of the series. On April 25th the top dressing of sulphate of ammonia was "applied in experiment 3.

"By May 24th further differences were noticeable; the 'equivalents' were in most cases rather stronger "than the corresponding sludges. Of the sludges, No. 2 alone seemed no better than the untreated lot, the "others generally showing improvement. Growth was rapid from now, and in each case the 'equivalents' "went to the front, and by June 20th Sludge No. 2, which up to then had been behind the others, now shot "ahead and was the best of the sludges. Sludges 4 and 6 had very irregular plants. As the ripening pro- "ceeded, the most noticeable point was that the straw was distinctly shorter in the case of the 'equivalents' "than with the sludges themselves; this held good in every case. The untreated lots ripened off first, then "the sludges, and lastly the equivalents. Photographs and measurements of the plants were taken just before "harvesting, this latter being done on August 28th, the corn being subsequently threshed out and weighed."

261. Having set out the results in tabular form and examined the results in detail, Dr. Voelcker draws the following conclusions :—

"(1) That the different sewage sludges, when used in sufficient quantity to supply 40 lbs. "of nitrogen per acre, are capable of increasing the yield of both corn and straw by 10 to 12 per "cent. above the unmanured produce.

"(2) That 'artificial equivalents' of the different sewage sludges applied as above will give "rather better results, the increase in corn and straw being 16 to 17 per cent. over the unmanured "produce."

"(3) That the tendency of the use of sewage sludges is to produce a greater length of straw."

"(4) That as between different sludges, those have done the best which contain the most "moisture and the most lime."

"(5) That the value of the sludge does not turn mainly upon the amount of nitrogenous organic "matters contained, but that these may, indeed, be in a form incapable of ready assimilation and "requiring lime for their decomposition."

"(6) That from a practical point of view none of the sewage sludges used would be worth 10s. "a ton on the farm for wheat-growing purposes."

262. Acting on the suggestions of Mr. Middleton and Dr. Voelcker, we have decided to continue these experiments for another year. The indications are that the manurial constituents of sewage sludge act much more slowly than those of ordinary artificial manures, and for this reason the second year results may be of considerable importance.

Unit for unit the nitrogen and the phosphoric acid of sludge seem to be of less value, manurially, than the nitrogen and phosphoric acid of artificial manures; at any rate so far as the first year of application is concerned. It also appears that sewage sludge is not a suitable dressing for quickly growing plants, unless it is applied in very large quantities per acre.

The important practical consideration, however, is not whether the manurial constituents of artificial manures are, unit for unit, more valuable than the manurial constituents of sewage sludge, but whether a given increase of crop can be produced more cheaply with sewage sludge than with artificial manures. Sewage sludge has undoubtedly a manurial value, but the manurial constituents being of necessity mixed with such a large proportion of grit, etc., the question of its economic use as a manure depends, to a large extent, upon the cost of carriage.

In the case of sewage sludge, likely to contain anthrax spores, it would of course be unwise to apply it to land. It would, however, be only in rare cases that such spores would be apt to be present.

SLUDGING OF MILL DAMS.

263. Our attention has been drawn to the evils attending the practice of the sludging of mill dams on rivers, and, although the matter is not directly within our terms of reference, we thought it desirable to take some evidence in regard to it, as it was alleged that the practice frequently gave rise to serious nuisance.

Many of the rivers in this country, particularly in Cheshire, Lancashire, and Yorkshire, are largely used by manufacturers for power and other purposes, and to facilitate the use of the water for such purposes, dams or reservoirs are constructed either in the bed of the stream itself, or near thereto.

In course of time, the mill dams become silted up with solid matters which are brought down in suspension by the stream, and which, owing to the velocity of the stream being reduced, settle in the mill dam. It is necessary to empty these solid matters out of the mill dams from time to time, and the evidence shows that when the accumulations are sent down the river in bulk serious pollution may take place and a nuisance may be caused. The liability to nuisance is of course greater in the case of rivers which, in their course above the mill dams, receive polluting matters such as sewage and manufacturing effluents, but it was represented to us that nuisance also occurs, though in a lesser degree, on rivers which are not so polluted.

Somerville, 20230–4, 20254–5. Tatton, 20264. Halliwell, 20477–86. Wilson, 23915, 23935–6. Tatton, 20265–73. Wilson, 23934.

The witnesses whom we examined specially in regard to these matters were :—

Mr. Herbert Hughes, C.M.G., Clerk of the Millowners' Association of the River Don.

Mr. J. Selwyn Rawson, Millowner.

Mr. A. F. Somerville, Chairman of the Sanitary Committee of the Somerset County Council.

Mr. R. A. Tatton, Chief Inspector of the Mersey and Irwell Joint Committee.

Mr. E. Halliwell, Chief Inspector of the Ribble Joint Committee.

Mr. H. Maclean Wilson, Chief Inspector of the West Riding of Yorkshire Rivers Board.

From the evidence of these witnesses, we find that there are three principal methods of removing the accumulations of solid matters, or sludge as it is termed, from dams, namely, (*a*) by opening the sluices and allowing the accumulated water to flush out the sludge ; (*b*) by turning the water of the stream through the dam and employing men to push and carry the sludge into the current of water, by which it is washed out of the dam into the stream ; and (*c*) by running the water out and wheeling the sludge to a tip outside the dam.

264. The main provisions of the general law affecting this matter are contained in the Rivers Pollution Prevention Act, 1876. There are, besides, two special Acts, namely, the Mersey and Irwell Joint Committee Act, 1892, in force in the area under the jurisdiction of the Mersey and Irwell Joint Committee ; and the West Riding of Yorkshire Rivers Act, 1894, in force in the area under the jurisdiction of the West Riding of Yorkshire Rivers Board.

By Section 2 of the Rivers Pollution Prevention Act, 1876, it is provided that "every person who puts or causes to be put or to fall, or knowingly permits to be put or to fall into any stream, so as . . . . . to interfere with its due flow, or to pollute its waters, the solid refuse of any manufactory, manufacturing process or quarry, or any rubbish or cinders, or any other waste or any putrid solid matter, shall be deemed to have committed an offence against this Act." By Section 17 the Act is not to apply to or affect the lawful exercise of any rights of impounding or diverting water ; and by Section 20, the term "solid matter" if not inconsistent with the context, does not include particles of matter in suspension in water.

The effect of these provisions upon the sludging out of mill dams has been the subject of a judgment in the Court of Appeal in the case of Ribble River Joint Committee *v.* Halliwell. The respondent owned a mill on the river Darwen, and he had from time to time been accustomed to divert the water, which was polluted with

vegetable substances, into a reservoir. The water was impounded in the reservoir, cleared, run off, and then used for condensing purposes. A large deposit was left at the bottom of the reservoir, and from time to time sluice gates were lifted and the deposit was discharged into the river. The matter so discharged was putrid, and it no doubt polluted the river.

The Court of Appeal held that the lawful exercise of the right to impound and divert water, which was protected by Section 17 of the Act of 1876, necessarily implied a right to return the water after it had been used for the purposes for which such right of impounding and diverting was so exercised; and that if, by the impounding, solid matter which was brought down in suspension by the stream was allowed to settle and become putrid, the return of the water, together with such putrid matter, was not an offence under Section 2 of the Act.

265. In the Mersey and Irwell Joint Committee Act, 1892, the prohibition against the putting of solid matters into a stream is extended to "sludge"; but it is provided that no person shall be deemed to have committed an offence against the Act for constructing in or across any "river or stream any . . . dam . . . which but for the passing of the Act he would have a legal right to construct," or "for putting into any such river or stream any sand or gravel or other natural deposit which shall have flowed from or been deposited by the current of any such river or stream."

So far as we are aware, the effect of the Mersey and Irwell Joint Committee Act has not been determined by the High Court; but it was stated by Mr. Tatton, then Chief Inspector of the Joint Committee, that proceedings had been taken under the Act in seven cases against millowners on polluted streams for sludging out mill dams, and that convictions were obtained in all these cases.

Tatton, 20305.

266. The West Riding of Yorkshire Rivers Act, 1894, follows closely the Mersey and Irwell Act, but is, if anything, somewhat stronger. For in addition to "sludge," the West Riding of Yorkshire Act expressly mentions "any rubbish or any deposit in a reservoir, mill dam, water lodge, or pond," as amongst the solid matters which may not be put into a river; and, while it contains the proviso that no person shall be deemed to have committed an offence for putting into a river or stream any sand or gravel or other natural deposit which shall have flowed from or been deposited by the current of the river or stream, it further provides that the sand or gravel or other natural deposit so put back into the stream shall not interfere with the due flow of or pollute the waters of such river or stream.

The West Riding Act has been before the High Court in the case of West Riding of Yorkshire Rivers Board *v.* Goldthorpe and another, which was an appeal by the Rivers Board from the decision of the Quarter Sessions dismissing a case in which a millowner was proceeded against for putting solid matter into a stream. From the report in *The Times* of June 9th, 1898, we gather that the process of the respondents was to collect in the mill dam the water that worked the mill by reason of which a deposit was created. Periodically this deposit was shovelled out into the stream and allowed to be washed down. Evidence was given that as much as 300 tons in one day was thus sent down, and a sample of dark coloured water was put in in evidence. The Court held that the section of the Act prohibiting the putting of solids into a stream did not apply to "cleaning out" a natural deposit of a mill dam. Day, J., stated "that was a natural deposit ordinarily associated with a mill pond when the water was torpid for a certain time. This was not an offence under the section, and, if it were, it would come within the exception."

We may also refer to another action under the West Riding of Yorkshire Rivers Act, viz., West Riding of Yorkshire Rivers Board *v.* Rawsons (1903). The respondents were the owners and occupiers of a mill situated on the bank of a river. Adjoining the mill was a large dam fed by a goit from the river and a tributary stream and having an outlet at the other end into a lower part of the river. The sewage from some 400 houses, besides the treated trade effluents of six mills, entered the river above the dam. Owing to the waters being impounded in the dam, a deposit of mud and sludge had formed in the basin of the dam. The respondents, in order to get rid of the mud-sludge and deposit, opened the sluice at the outlet of the dam and turned the whole of the waters of the river through the dam, while men with spades conveyed and scraped the mud, sludge and deposit into the current so made when it was carried in suspension through the outlet, making the river muddy and unfit for any purpose.

It was held that the respondents had committed no offence under the Act. In the course of his judgment, Wills, J., stated, "under the Act applicable to the present case the sludge is prohibited from being sent out, but, by reason of what has been done, the sludge before anything has been sent out has ceased to be sludge, or has been converted into a very mild decoction." This had reference to the fact that a sample of the water taken at the outlet during the sludge operations was analysed and found to consist of slightly over 99½ per cent. of liquids and less than half per cent. of solids in suspension.

267. It was clearly the intention of the two Rivers Boards, in promoting their special Acts, to obtain power to prevent millowners from turning into the river the solid matters which had been deposited in mill dams, and it was urged by some of the witnesses that the general law should be altered so as to prohibit the scouring out of the sludge into the river, save perhaps in exceptional cases, and that the manufacturer should be required to remove the sludge on to land. Mr. Maclean Wilson, representing the West Riding of Yorkshire Rivers Board, stated that, on the whole, this was the more common practice in the West Riding, and that therefore it must be regarded as a financially practicable method to adopt. Mr. Tatton, Chief Inspector of the Mersey and Irwell Joint Committee, and Mr. Halliwell, Chief Inspector of the Ribble Joint Committee, expressed a similar view.

Somerville, 20251. Tatton, 20286–7, 20318–9. Halliwell, 20503–5. Wilson, 23918–21, 23939–44, 23939–42. Tatton, 20331–2. Halliwell, 20505–6.

On the other hand, Mr. Hughes, representing the Millowners' Association of the River Don, contended that the cost of removing the sludge on to land would in some cases be absolutely prohibitive, and this view was supported by the evidence of Mr. Rawson, a millowner. It was further pointed out that in some cases the situation of the mill dam would render it impracticable to remove the sludge on to land.

20124. 20183–99. Rawson, 20184–6 Halliwell 20515–7.

268. We are satisfied that the discharge of sludge from mill dams into the river, at more or less lengthy intervals of time, in some cases gives rise to serious evils. While the river could itself deal with the suspended matters as they flow down from day to day, it cannot cope with the accumulation of such matters when these are discharged altogether over a short period.

At the same time it must be remembered that in numerous case millowners have had the unrestricted right for many years to empty the sludge from their dams into the river, and that any undue interference with this right might seriously affect industries.

Looking to all the circumstances, and having regard to the evidence given on behalf of millowners, we do not consider that the practice of sludging mill dams by turning the accumulations into the stream should be absolutely prohibited by law in every case without regard to the local circumstances. We are of opinion, however, that in most cases it would be financially practicable for the millowner to remove the sludge on to land or to adopt some other means of disposing of it, and in such cases the millowner should not be allowed to turn it into the stream if, by so doing, a nuisance would be caused.

Recommendation.

269. We recommend that in any case in which the Rivers Board should be of opinion that the sludging of a mill dam by turning the accumulated sludge into the stream would give rise to nuisance, and that it would be financially practicable for the mill owner to adopt some other method of cleansing the dam, the Rivers Boards should be empowered, by notice, to direct the millowner not to turn the sludge into the stream.

It should be provided that any millowner deeming himself aggrieved by such a direction, might, within some fixed period, appeal to the Central Authority. The decision of the Central Authority should be final.

Should any cases arise in which it is important that the sludge should not be turned into the stream, but in which the Rivers Board are of opinion that the cost of adopting any other method of cleansing the dam would be prohibitive to the millowner, we recommend that the Rivers Board should be empowered to represent the case to the Central Authority, and that the Central Authority should be empowered, after due inquiry, to direct that the sludge shall not be turned into the stream. If the Central Authority should be satisfied that the cost of adopting some other method of cleansing the dam would be greater than the millowner could be reasonably called upon to bear, they should be empowered to direct that a portion of the cost should be borne by the local authorities whose districts would be benefited.

PART V.—GENERAL.

EFFECT OF TRADE EFFLUENTS ON SEWAGE PURIFICATION.

270. All the trade effluents of which we have had experience interfere with or retard processes of purification to some extent, but we are not aware of any case where the admixture of trade refuse makes it impracticable to purify the sewage either upon land or by means of artificial processes, although in certain extreme cases special processes of preliminary treatment may be necessary.

In the following cases, which we have investigated more or less fully, some modifications have had to be adopted in consequence of the presence of trade refuse.

Burton-upon-Trent.—Brewery refuse.

Here the sewage consists mainly of brewery refuse, the sewage proper constituting only about one-fifth part of the whole. We are not aware whether artificial processes of treatment have been tried with the Burton sewage; but, for its treatment on land, the addition of a very large quantity of lime has been found necessary (40 to 50 grains per gallon), otherwise the decomposition of the sewage gives rise to the production of much sulphuretted hydrogen, causing great nuisance. With carefully regulated addition of lime, treatment on land appears to be successful in producing a good effluent.

Bradford.—Wool-scouring liquor.

The sewage of Bradford contains a large proportion of wool-scouring liquors, which have the effect of making it abnormally alkaline and very greasy. A special preliminary process of precipitation has therefore been found necessary, viz., the "cracking" of the sewage with sulphuric acid. The fats which are thus set free are extracted from the precipitated sludge by pressing hot, and by distillation of this pressed sludge under reduced pressure. The precipitation liquor after the addition of sulphuric acid can be successfully treated on percolating filters at rates of from 50 to 100 gallons per cube yard per day, notwithstanding that it is often distinctly acid as it goes on to the filter. It may be added that the effluent from the filters is usually neutral or slightly alkaline.

Rochdale.—Wool-scouring liquor, waste liquor from fellmongers, rubber-recovery waste.

At Rochdale, as at Bradford, the sewage is often rendered very alkaline and greasy by the discharge of wool-scouring liquor. At such times sulphuric acid in addition to alumino-ferric is used as a precipitant; otherwise the tank liquor obtained is unsatisfactory and badly settled. The sewage after precipitation is successfully treated, either upon filters, or upon land.

It is interesting to note that the strong alkaline sewage at Rochdale can be successfully treated, without any neutralisation, by septic tanks, followed by Whittaker percolating filters.

Wolverhampton.—Waste liquors from galvanising works.

Owing to the discharge of the "used-out" liquors and wash water (which contain a large quantity of ferrous iron in acid solution) from the vats at the galvanising works in the town, the Wolverhampton sewage is often mixed with such a large quantity of this liquor that it is then necessary to increase the quantity of lime which

is used as a precipitant in order to obtain good settlement in the tanks. If sufficient lime is added, the iron in the sewage helps the precipitation. The tank liquor is successfully treated over land, and it has also been shown, by experiment, to be easily amenable to treatment on bacteria beds.

There are many similar cases; but those cited are, perhaps, sufficient to show that trade effluents may render necessary modifications in the ordinary processes of purification.

271. These cases may, we think, be regarded as more or less exceptional. Usually we find that the amount of trade effluent is not sufficiently large to make any material modification of the *process* necessary, though of course the increase in volume of the sewage to be treated may necessitate an enlargement of the filtering area. The following are cases of this kind :—

Birmingham.—Various manufacturing liquors.

The Birmingham sewage, notwithstanding the considerable proportion of various manufacturing waste liquors which it contains, can be successfully treated upon land or upon artificial filters, after ordinary preliminary settlement and septic tank treatment.

Manchester.—Various manufacturing wastes, including many tar products.

Here part of the sewage is being successfully treated on a large scale by means of septic tanks and contact beds.

Leeds.—Wool fibre, dye waste, tannery and iron liquors.

The fibrous nature of the suspended matter in the Leeds sewage and the amount of finely divided and colloidal iron compounds which it contains seem to be the main causes which render the settlement—either by septic tank treatment or sedimentation, or even by precipitation—more difficult, and the danger of filter clogging much more serious, than would be the case if these waste products were absent. The trade effluents in general also seem to have the effect of inhibiting, to some extent, the action of the nitrifying organisms in the biological oxidation processes at Leeds, for it has been noticed that filters take an exceptionally long time to mature there.

The experiments at Leeds, however, have shown that it is possible to produce good effluents by various processes, and that—with careful selection of the materials—clogging can be prevented long enough to make it practicable to treat the sewage by artificial filtration.

Maidstone.—Brewery and tannery waste.

The Maidstone sewage is frequently mixed with large quantities of the waste liquors from breweries and tanneries. At such times the liquid resulting from the tank treatment after precipitation with lime is organically stronger and less well settled than at other times. The trade effluents at Maidstone also appear to have the effect of increasing the nuisance from the tanks, for it has been noticed that when these liquors are present the smell is much greater. Experiments, worked partly under our observation for this special purpose, have shown that the sewage can be purified to the extent of 88 per cent., calculated on the "oxygen absorbed" in four hours, by double contact filtration, without preliminary treatment in tanks for the settlement of the solids, although only a small quantity (23·7 gallons) can be filtered per cube yard per day.

Yeovil.—Waste liquors from tanneries.

At Yeovil, closed septic tanks and double contact beds appear to be successful in treating a sewage which is often mixed with a large proportion of tannery liquor.

Here the effect may be to require a more frequent cleansing of the tanks and possibly of the filter beds. We have not watched the plant continuously.

York.—Tannery waste and waste-waters from a confectionery works.

After septic tank treatment the York sewage can be successfully treated upon percolating filters at a rate of something like 150 gallons per cube yard per day.

There are a number of such cases, and, indeed, the great majority of sewages from towns with populations from 5,000 upwards are mixed with small proportions of manufacturing wastes. Generally, therefore, we are satisfied that the character and proportion of the trade effluent or effluents in the sewage are not such as seriously to affect any process of purification, though in some cases where it is present in large proportion, or is of a specially refractory character, special means have to be taken to counteract its influence.

At many of the places which we have visited (for example, Birmingham, Bradford, Burton, Burnley, Huddersfield, Leeds, Manchester) the difficulties arising from the admixture of trade effluent with the sewage have been largely overcome as the result of experiments, which have been conducted under the supervision of skilled scientific advisers resident upon the works.

272. Our further experience strengthens the view which we expressed in our Third Report, that, as a general rule, trade effluents should be allowed to enter the sewers, but that the local authority should be given power to require that their admission should be subject to regulation.

NUISANCE FROM SMELL AT SEWAGE WORKS.

273. All sewage works are liable, at times, to give off unpleasant smells, and they should, therefore, be situated away from dwelling houses, wherever this is practicable.

The nuisance is apt to be considerably greater where the sewage contains brewery refuse in any quantity; but, on the other hand, the presence of some trade effluents, such, *e,g.*, as iron salts or tarry matters, tends to render the process of purification less offensive.

The extent of the risk of nuisance depends, however, not only on the character of the sewage, but also on the method of treatment adopted.

Tank Treatment.

274. Septic tank treatment is likely to be more offensive than chemical precipitation or simple sedimentation. During sludging operations all tanks are usually offensive; but septic tanks—unlike other tanks—may give off sulphuretted hydrogen, and probably small quantities of offensive organic sulphides, at other times.

By covering over septic tanks and the feed channels to the filters, the risk of nuisance from the tanks themselves during the period of working is greatly lessened, but the liquor issuing from septic tanks contains a larger amount of sulphuretted hydrogen than other tank liquors, and its subsequent filtration may, therefore, give rise to more nuisance.

Filters.

275. The exposure of a foul smelling liquid to the air is necessarily accompanied by risk of nuisance, and if such a liquid, in the process of distribution, is divided up into small drops or jets, it is obvious that the smell will be greatly intensified.

For these reasons percolating filters are more likely to give rise to nuisance than contact beds, if the liquid to be treated contains offensive gases.

In some cases, septic tank liquor can be treated upon percolating filters without much risk of nuisance, but where the liquor is derived from a strong domestic sewage or a domestic sewage containing brewery or tannery waste, and especially if it is sprinkled or sprayed upon percolating filters, serious smell may occur in the neighbourhood of the works.

At the following places where septic tank liquor is sprinkled upon percolating filters, there is usually a considerable smell in the proximity of the filters :—

Accrington	Strong domestic sewage.
Dorking	Domestic sewage of about average strength.
Guildford	Very strong domestic sewage containing brewery waste.
Dorchester	Domestic sewage containing brewery waste.

On the other hand the same process does not give rise to any serious complaint at :—

Birmingham	Strong sewage containing much manufacturing waste, which includes salts of iron.
Huddersfield	Rather weak sewage containing much manufacturing waste, including salts of iron.
Leeds	Rather weak sewage containing much manufacturing waste, including salts of iron.
Hanley	Weak sewage containing a small proportion of manufacturing waste.

Where fresh crude sewage or fresh precipitation liquor is treated upon percolating filters, there is much less danger of nuisance. This is exemplified at the following places :—

Crude Sewage :

Hendon	Domestic sewage of average strength.
Leeds	Rather weak sewage containing much manufacturing waste.

Settled Sewage :

Huddersfield - -	Rather weak sewage containing much manufacturing waste.
Leeds - - -	Rather weak sewage containing much manufacturing waste.
Market Drayton -	Very strong slopwater sewage.

Precipitation Liquor :

Kingston - - -	Domestic sewage containing a small proportion of trade waste.
Dorking - - -	Domestic sewage of about average strength.
Chorley - - -	Domestic sewage of about average strength.
Royton - - -	Domestic sewage.
Normanton - -	Very strong slopwater domestic sewage.
Withnell - - -	Strong domestic sewage, mainly slopwater.

At Horfield, however (strong domestic sewage, partly derived from latrines), where precipitation liquor was distributed by dripping trays upon percolating filters, there was occasionally a very strong local smell upon the works.

276. Our experience leads us to the following general conclusions upon this question:—

That where weak sewage, purely domestic or mixed with manufacturing refuse, is treated either fresh or after chemical precipitation, or even after passing through septic tanks, there is not likely to be any serious smell. If such a sewage contains a small proportion of brewery or tannery waste, however, and is given preliminary treatment in septic tanks, nuisance may possibly arise if the septic liquor is sprinkled or sprayed upon percolating filters.

That where a strong domestic sewage is treated, either fresh or after settlement or chemical precipitation, by sprinkling upon percolating filters, and especially if it is a slopwater sewage, there will not be much danger of nuisance.* On the other hand, if such a sewage is passed through septic tanks, there will be danger of serious nuisance, while if it contains brewery or tannery waste there will be danger of nuisance with any form of preliminary treatment, excepting possibly chemical precipitation.

That with a weak sewage, containing a mixture of trade wastes (especially if iron salts are present), there will be little danger of nuisance, whatever the form of preliminary treatment or final filtration.

That with a strong sewage containing a mixture of trade wastes, there will not be much danger of nuisance, if it is treated by sprinkling upon percolating filters in the fresh state or after simple subsidence or chemical precipitation; but, if it is first passed through septic tanks, there may in some cases be serious danger of nuisance. This was well exemplified in the case of the experimental septic tank at Sheffield, even though the sewage there contained considerable quantities of iron salts.

The risk of nuisance with percolating filters depends to a large extent on the method of distribution adopted, unless the filter is covered in.

277. The following table shows a number of places arranged in the order of "strength" of sewage, side by side with our observations as to nuisance arising from the distribution of the liquid over the filters:—

* This might not hold good in the case of highly ammoniacal sewages.

Place.	Nature of Sewage.	*Calculated strength of sewage.	Nature of preliminary treatment.	Distributor.	Remarks as to smell arising from the distribution.
Places where smell is apparent.					
Rochdale -	Strong domestic sewage, mixed with large quantities of wool-scouring liquor.	203	Septic tank.	Sprinkler.	Considerable smell in neighbourhood of filter.
Caterham -	Very strong domestic sewage, derived mostly from latrines.	195	Septic and "cultivation" tank.	Perforated pipes.	Strong smell in filter house.
Guildford -	Very strong domestic sewage, mixed with brewery waste.	194	Septic tank.	Sprinklers.	Strong smell in neighbourhood of filter.
Accrington -	Rather strong domestic sewage.	121	Septic tanks.	Sprinklers.	Strong smell near filters as a general rule.
Dorking -	Domestic sewage of about average strength.	96	Septic tanks.	Sprinkler.	Strong smell near filters.
Horfield -	Domestic sewage, derived partly from latrines.	88	Precipitation tanks.	Dripping trays.	Occasionally very strong smell near filters.
Knowle -	Domestic sewage.	78	Septic tanks.	Dripping trays.	Occasionally some smell near filters.
Places where little smell is apparent.					
Clifton - -	Very strong slopwater sewage.	247	Settling tanks.	Fine material on surface.	Very little smell from filters.
Normanton -	Very strong slopwater sewage.	235	Precipitation tanks.	Fine material on surface.	Very little smell from filters.
Little Drayton	Very strong slopwater sewage, containing laundry waste.	205	Settling tanks.	Tipping troughs.	Very little smell from filters.
Birmingham -	Strong trade sewage, containing salts of iron.	—	Septic tanks.	Nozzles.	Very little smell from filters.
Leeds - -	Trade sewage, strong as regards suspended matter, but otherwise rather weak.	123	Septic, settling and precipitation tanks.	Sprinklers.	Very little smell from filters.
York - -	Rather weak domestic sewage, but containing tannery waste, etc.	115	Septic tanks.	Sprinklers.	Very little smell from filters.
Hendon -	Domestic sewage of about average strength.	110	No preliminary treatment.	Tipping troughs.	Very little smell from filters.
Chorley -	Domestic sewage of about average strength.	106	Precipitation tanks.	Flushing over fine material on surface.	Practically no smell from distribution.
Dorking -	Domestic sewage of about average strength.	96	Precipitation and settling tanks.	Sprinklers.	Very little smell from filters.
Kingston -	Domestic sewage of about average strength.	94	Precipitation tanks.	Sprinkler.	Practically no smell from distribution.
Salford - -	Trade sewage of about average strength.	—	Precipitation tanks.	Nozzles.	Very little smell from distribution.
Hanley - -	Weak domestic sewage, containing a small proportion of trade waste.	61	Septic tanks.	Sprinklers.	Very little smell from filters.
Prestolee	Very weak slopwater sewage.	28	Septic tanks.	Fine material on surface.	Very little smell from filters.

(* See p. 15 of this report and the memorandum of Dr. McGowan in Appendix IV.)

278. In the whole of our experience with contact beds, we have only observed one case in which any appreciable nuisance arose after the liquor to be treated was in the bed.

In that case the nuisance was, we think, due to overworking, for the smell practically disappeared when the beds were given a short rest.

On the other hand, there is almost always local smell from the channels or feed troughs delivering to a contact bed, when the liquid to be treated possesses a strong smell, and also, in some cases, when the primary bed is being discharged.

At Hampton, during the last year of the treatment of crude sewage upon contact beds, the filling of both primary and secondary beds was attended with local smell. In the case of the primary beds, we think that there would have been serious nuisance if there had been houses in close proximity to the works. In this case, the smell chiefly arose from the settling " bays " constructed on the surfaces of the beds.

At Guildford, Hartley Wintney, Andover, Exeter (Main Works), Ilford, Leeds, Bradford, and Sheffield, we have, on a number of occasions, been aware of considerable local smell arising from feed channels during the filling of contact beds. If steps are taken to obviate this, there is no doubt that contact beds are less liable to give rise to nuisance than any other form of filters.

In connection with the smell which arises from feed channels and distribution pipes, it is of interest to observe that at Ilford and Andover the authorities have recently adopted the plan of covering the channels and laying a few inches of material over the distribution pipes. We understand that this has had the effect of reducing the smell to a very large extent.

An important point which is sometimes lost sight of is that, although the surfaces of contact beds are rich in insect life, it is unusual to see many flies on the beds, whereas percolating filters of coarse or medium material generally swarm with them.

Treatment on Land.

279. Where the soil is fairly porous and the land is not overworked, land treatment of sewage is not, as a rule, offensive.

In certain states of the atmosphere, however, we find that the smell from sewage farms is offensive, and it is therefore important that sewage farms, also, should be kept as far away from dwelling houses as practicable.

Deodorization of Septic Tank Liquors.

280. The use of septic tanks followed by percolating filters, may, in some cases, be the most economical way of treating the sewage, but in view of the greater risk of nuisance from such a combination, it might not be advisable to adopt it in many cases.

The question whether the offensive character of septic tank liquors might be destroyed, arose in the case of Stone, in Staffordshire, where a sewage containing brewery refuse had to be dealt with. In that case it was proposed to overcome the difficulty by the addition to the septic tank liquor of an active chlorine solution, *i.e.*, a solution of alkaline hypochlorite, produced by an electrical process by a company named " Oxychlorides, Limited."

The addition of this chlorine solution clearly lessened the offensive smell of the septic tank liquor, but the question was raised whether it might not also interfere with the subsequent oxidation of the sewage by filtration.

For the purpose of testing this by experiment, two identical percolating filters were provided at the Guildford sewage works, and these were kept under observation for several months by Mr. Carter, Assistant Chemist to the Commission. On to one of these filters was run septic tank liquor alone; on to the other, the same tank liquor, in the same amount, but mixed with varying quantities of the hypochlorite solution.

The results of these experiments showed :—

1. That "35* per cent. to 50 per cent. treatment" with the hypochlorite solution is sufficient to do away with the offensive sulphuretted hydrogen smell of the Guildford septic tank liquor, leaving in its place a comparatively inoffensive odour of spent bleach and fresh sewage.

2. That the addition of this quantity of "oxychloride" in no way interferes with the efficiency of the filter. Indeed, it rather adds to it, by helping to keep down an excess of grey growths on the top of the filter.

3. That a very much larger quantity of oxychloride *may* be added, without any danger to the filter. In other words, there is a large margin of safety, so far as regards the accidental addition of too much oxychloride. Somewhere between "200 per cent. and 500 per cent. treatment" appears to be the limit of the quantity of oxychloride which can be added with safety.

A number of bacteriological examinations were also made in connection with the experiments, and we ascertained that a dose of oxychloride *more* than sufficient to remove a sulphuretted hydrogen smell and kill *B. coli* in the liquid to be treated may be used without prejudice to the purifying ability of a *mature* percolating filter.

A summary of the experiments is given in the accompanying table, and a detailed Report upon them in Appendix IV.

* As to the meaning of this term *see* Mr. Carter's Report, Appendix IV.

Date and Duration of Experiment.	% Treatment	Effect of Treatment as regards Smell of Tank Liquor.	Effect of Treatment as regards Purification by the Filter.	Nitric Nitrogen. Parts per 100,000. Effluent from Untreated Tank Liquor. †	Nitric Nitrogen. Parts per 100,000. Effluent from Treated Tank Liquor. †
				Average.	Average.
Nov. 22nd to Dec. 5th, 1906 (14 days).	25 %	Tank liquor rendered much less offensive, owing to the destruction of about four-fifths of the total sulphuretted hydrogen present.	Quality of the effluent unaffected. The effluent had a slight spent bleach liquor odour.	1·41—2·41=2·07 (8)	1·33—2·74=2·15 (8)
Dec. 6th to 10th, 1906 (5 days).	35 %	This increase of dose was too small to make any marked difference from the 25 % treatment. The tank liquor still possessed a slight septic odour, the sulphuretted hydrogen not being entirely eliminated.	Quality of the effluent unaffected.	1·95—1·98=1·97 (3)	1·95—2·00=1·97 (3)
Dec. 11th to 21st, 1906, and Dec. 31st, 1906, to Jan. 13th, 1907 (25 days).	50 %	This dose completely destroyed all the sulphuretted hydrogen present. The tank liquor possessed a slight fresh sewage smell with an accompanying spent bleach liquor odour, and was not offensive.	Quality of the effluent unaffected.	1·25—2·78=2·13 (15)	1·29—3·63=2·23 (15)
* Feb. 15th to May 13th, 1907 (87 days).	100 %	With this dose there was an excess of oxychloride in the tank liquor going on to the filter. The sewage smell was masked by the spent bleach liquor odour. The average excess of oxychloride was equal to 1·00 parts of available chlorine per 100,000.	Taking the figures for analysis over the whole time, there was very little difference between the quality of the two effluents. This experiment was started in very cold weather, and at first the effluent from the filter taking the treated liquor was inferior in quality to the effluent from the filter taking the untreated liquor. As the weather became warmer, both effluents improved.	0·60—5·82=2·38 (66)	0·21—5·81=2·59 (66)
May 14th to 30th, 1907 (17 days).	200 %	The tank liquor was bleached considerably by this dose.	Quality of the effluent unaffected.	4·10—6·21=4·84 (13)	4·10—6·46=4·92 (13)
May 31st to June 10th, 1907 (11 days).	500 %	This dose bleached the tank liquor to a pale yellowish colour. The average excess of oxychloride amounted to about 12–16 parts of available chlorine per 100,000.	The quality of the effluent was appreciably affected by this dose, both as regards appearance and the amount of Nitric Nitrogen.	4·62—5·98=5·26 (10)	2·90—5·05=4·00 (10)
June 11th to July 12th, 1907 (32 days).	1,000 %	The tank liquor was completely bleached by this dose and possessed a strong spent bleach liquor odour, owing to the large excess of oxychloride (about 30 parts of available chlorine per 100,000).	The quality of the effluent was immediately affected by this dose, the Nitric Nitrogen being reduced by about 50 per cent. In a fortnight it had disappeared entirely and the effluent was very thick and turbid in appearance, and on testing gave a reaction for available chlorine.	4·22—5·85=4·91 (14)	0·00—2·70=1·17 (14)

* From March 5th, 1907, the conclusions have been based on data supplied by Mr. Fieldhouse, Manager at Guildford for Oxychlorides, Ltd.
† Figures in brackets represent the number of samples analysed.

The Oxychloride Company has furnished the following figures as representing the working cost of deodorising 1,000,000 gallons of septic tank liquor by the addition of 6 gallons, 8·4 gallons, and 12 gallons of strong oxychloride, respectively, per 100,000 gallons of liquor :—

Amount of Oxychloride added.	Working cost per million gallons.	
	s.	d.
6 gallons per 100,000 gallons - - - -	9	3
8·4 „ „ „ - - - -	12	2
12 „ „ „ - - - -	18	6

The capital cost of the plant would be the same in each case. For the Guildford sewage, this was calculated to be £1,220.

281. Of course, there are other ways of providing chlorine, if it should be found that this is the best body to use for the purpose of destroying the offensive character of septic tank liquor.

Our own experiments have shown that the offensive character of Dorking septic tank liquor can be destroyed by the addition to it of 3 grains of lime per gallon. We have also found that the liquor, so treated, could, after a short settlement, be filtered at a considerably increased rate.

Generally, we may say that the risk of nuisance at a sewage works may be considerably lessened by careful selection of the method of treatment and careful attention to details; and that by the adoption of special precautions, methods of treatment, which ordinarily are accompanied by somewhat serious smell, may be rendered almost inoffensive.

SOME OBSERVATIONS ON THE CHOICE OF A METHOD OF SEWAGE TREATMENT.

General.

282. The selection of a method of sewage disposal, and the settlement of details in connection with any method which it is proposed to adopt, should depend primarily on local conditions, and we only propose to indicate in a general way what, in our opinion, should be the guiding considerations.

In a later part of this Report,* we have expressed the view that the degree of purification which should be required in any particular case should depend on local circumstances, and the question which a local authority would have to determine would be in what way the sewage could be most economically purified to the extent necessary. If a sufficient quantity of good land, to which the sewage can flow by gravitation, can be purchased for about £100 an acre, land treatment would, we think, usually be the cheapest method to adopt. Or, if the case were one in which it was necessary to obtain a high class effluent, it might be cheaper to pay a somewhat higher price for good land, rather than to adopt artificial treatment, because effluents obtained from the treatment of sewage on artificial filters, as usually carried out in practice, are generally distinctly inferior to those obtained by the treatment of sewage on good land, and some addition to the ordinary artificial plant would therefore be required. On good land, a sewage of average strength, from which the major portion of the suspended solids have been eliminated by tank treatment, can be treated at about the rate of 30,000 gallons per acre per day, with the production of a high class effluent. If the land available were of only medium quality, capable, say, of treating only half this quantity, its use might still be economical, if it could be acquired at about £50 an acre.

In cases where only clay land was available, we think that it would generally be cheaper and more satisfactory to provide artificial filters.

In considering the question whether land or artificial treatment should be adopted, the situation and levels of the land available are, of course, important factors. And whatever system is adopted, it is essential that the works should be so situated as to be capable of extension.

Selection of an Artificial Process.

283. As regards the selection of an artificial process, the following are the broad generalisations at which we have arrived :—

Tank Treatment.

It has been shown in another section of our Report that, given conditions favourable to each process, there is little difference as regards cost between any of the different forms of tank treatment when the cost of the subsequent filtration is taken into account. For this reason, the selection of the preliminary process should depend mainly upon local circumstances and upon the facilities offered for the disposal of sludge.

If the circumstances were such that considerable quantities of sludge could be easily and effectively disposed of, say, as wet sludge by sending to sea or by trenching in soil, or as pressed cake by sale or gift to farmers, it would probably be best and cheapest to adopt a preliminary process which removed as much of the suspended matter as possible from the sewage. If, on the other hand, it were imperative to have as little sludge and as few sludging operations as possible, then septic tanks or continuous flow settling tanks might be cheaper. The size of the place and the question of smell † are also factors of primary importance in the selection of the preliminary process.

CLASS I.

Typical Analysis of Sewage from a water-closet town with a water supply of 25 to 30 gallons a head. Separate system of sewers.

Typical Analysis of Sewage from a slop-water town, having few water-closets, where the water supply is about 10 to 15 gallons a head, and where the sewers are on the partially separate system.

Strong or Very Strong Sewage.

Ammoniacal nitrogen	9·0
Oxygen absorbed in 4 hours	17·0
Suspended solids	40·0

Strength 160 to 170.

Ammoniacal nitrogen.	Oxygen absorbed in 4 hours.	Suspended solids.
7·5	20	40

Strength 175 to 200.

Ammoniacal nitrogen	6·0
Oxygen absorbed in 4 hours	25·0
Suspended solids	40·0

Strength 200 to 230.

Chemical precipitation and quiescent settlement for 2 hours.

Precipitation Liquor.

Ammoniacal nitrogen	7·0
Oxygen absorbed in 4 hours	8·0
Suspended solids	2 to 5

Strength 90.

Chemical precipitation and 8 hours' continuous flow settlement.

Precipitation Liquor.

Ammoniacal nitrogen	7·0 to 7·5
Oxygen absorbed in 4 hours	9·0
Suspended solids	8·0

Strength 95 to 100.

Quiescent settlement for 2 hours.

Settled Sewage.

Ammoniacal nitrogen	7·0 to 7·5
Oxygen absorbed in 4 hours	10·0
Suspended solids	10·0

Strength 100 to 105.

Continuous flow settlement for 15 hours.

Settled Sewage.

Ammoniacal nitrogen	7·0 to 7·5
Oxygen absorbed in 4 hours	12·0
Suspended solids	15 to 20

Strength 120.

Septic tanks. 24 hours' continuous flow.

Septic Tank Liquor.

Ammoniacal nitrogen	8·0 to 8·5
Oxygen absorbed in 4 hours	13·0
Suspended solids	15·0 to 20·0

Strength 130.

Effluents.

	Double contact beds.	Percolating filters of coarse material (deep).	Percolating filters of fine material (shallow).	Good land (Filtration with little cropping).
Rate of filtration per cube yard.	6 gallons. (2½ fillings)	150 gallons.	100 gallons.	25,000 to 30,000 gallons. per acre per day. (5 to 6 gallons. per sq. yd.).
Ammoniacal nitrogen	2·0	2·0	2·0 to 3·0	0·25
Nitric nitrogen	1·5	2·0	3·0	1·5
Oxygen absorbed in 4 hours	3·0	3·0	2·5	0·3 to 0·5
Suspended solids	2·0	4·0 to 5·0	2·0 to 3·0	Possible traces of growth, washed out from drains.

Variable effluents, sometimes putrescible.

Effluents.

	Double contact beds.	Percolating filters of coarse material (deep.)	Percolating filters of medium material (shallow.)	Good land (Filtration with little cropping).
Rate of filtration per cube yard per day.	50 gallons. (2 fillings)	100 gallons.	75 gallons.	25,000 gallons. per acre (6 gallons. per sq. yd.).
Ammoniacal nitrogen	2·0	2·5	2·5	0·25
Nitric nitrogen	1·5	2·0	2·0 to 3·0	1·5
Oxygen absorbed in 4 hours	3·0	3·0	2·5	0·3 to 0·5
Suspended solids	2·0	6·0	5·0	Possible traces of growth, washed out from drains.

Variable effluents, sometimes putrescible.

Effluents.

	Triple contact beds.	Percolating filters of coarse material (deep).	Percolating filters of fine material (deep).	Good land (Filtration with little cropping).
Rate of filtration per cube yard per day.	40 gallons. (4 fillings)	75 gallons.	35 gallons.	20,000 gallons. per acre per day (4 gallons. per sq. yd.).
Ammoniacal nitrogen	1·0	1·0	0·5	0·25
Nitric nitrogen	2·0 to 2·5	3·0	4·0	1·5
Oxygen absorbed in 4 hours	1·5	3·0	2·5	0·3 to 0·5
Suspended solids	Trace	6·0 to 8·0 and more.	5·0	Possible traces of growth, washed out from drains.

Fine material in tertiary beds.
Rate of filtration could not be doubled in wet weather.

Effluents.

NOTES.—(1) The numbers given for "strength" of Sewage represent *approximately* the parts by weight of oxygen required to oxidize 100,000 parts.
(2) "Oxygen absorbed in 4 hours" means oxygen absorbed in 4 hours at 27° C. (80° F.) from an eighth normal solution of permanganate of potash (3·94 grms. per litre), rendered acid with dilute sulphuric acid.
(3) All figures of analysis are stated in parts per 100,000.
(4) By a "deep" filter we mean one of 5 to 6 feet and upwards in depth; by a shallow filter one which is below 5 feet in depth and usually about 3 feet. It would probably be inadvisable at the present time to build sewage filters of a less depth than 2 feet 6 inches.
(5) At first sight it may seem curious that the same figures of analysis should be given for the land effluents of this Class. It has, however, to be remembered that the mechanical straining effect of land is such that all liquors derived from the same sewage must necessarily be brought more or less into line, and, further, that volume of sewage is a more important factor in land treatment than strength.
(6) The figures of analysis for effluents refer to the effluents including their suspended solids.

This sewage would be derived from a water-closet town, where the sewers were on the partially separate or the combined system, where the water supply was about 30 gallons per head, and where a moderate quantity of subsoil water gained access to the sewers.

CLASS II.

Sewage of about Average Strength.

Ammoniacal nitrogen.	Oxygen absorbed in 4 hours.	Suspended solids.
4·0	10 to 12	28 to 30

Strength 100.

Chemical precipitation and quiescent settlement for 2 hours.

Precipitation Liquor.

(2.) "Oxygen absorbed in 4 hours" means Oxygen absorbed in 4 hours at 27° C. (80° F.) from an eighth-normal solution of permanganate of potash (3·94 grms. per litre), rendered acid with dilute sulphuric acid.

(3.) All figures of analysis are stated in parts per 100,000.

(4.) By a "deep" filter we mean one of 5 to 6 feet and upwards in depth; by a "shallow" filter one which is below 5 feet in depth and usually about 3 feet. It would probably be inadvisable at the present time to build any sewage filter of a less depth than 2 feet 6 inches.

(5.) At first sight it may seem curious that the same figures of analysis should be given for the land effluents in this class. It has, however, to be remembered that the mechanical straining effect of land is such that all liquors derived from the same sewage must necessarily be brought more or less into line, and, further, that volume of sewage is a more important factor in land treatment than strength.

(6.) The figures of analysis for effluents refer to the effluents including their suspended solids.

Filters.

Single contact beds will, generally, only yield a good effluent where the sewage to be purified is weak, and then only after good preliminary treatment. For the purification of partially settled weak sewage and for well as also for partially settled sewage of average strength, if the case is one in which a good effluent is required, double contact is necessary, while, if a strong sewage has to be purified, triple contact is necessary unless the preliminary treatment is exceptionally good.

In nearly every case a greater rate of filtration can be adopted if the material is arranged in the form of a percolating filter than if it is used in contact beds. The rate of filtration per cube yard in the case of percolating filters may, generally, be double or nearly double that which is permissible in the case of contact beds.

As regards percolating filters, where the liquor to be treated is weak, and the preliminary treatment has effectively removed the greater part of the suspended matter, it is probably best, in most cases, to use fine material arranged in the form of shallow filters.

Where the sewage to be treated is strong, and especially if the preliminary treatment leaves a considerable quantity of suspended matter in the tank liquor, it is best to use deep filters of coarse material.

Where the liquor to be treated contains much suspended matter, it is usually advisable to construct percolating filters of coarse material, *whatever the strength of the original sewage.*

For sewages of about average strength, from which most of the suspended matter has been removed in the preliminary treatment, either coarse or fine material may be used.

It may be added that, with very well clarified weak sewage, filters with a top layer of very fine material, such as sand, can be made to give good results with a rate of filtration of 400 or even 500 gallons per cube yard per day. In this case, however, the materi l must be washed (*e.g.*, by upward flow of tank liquor) at short intervals of, say, a week.

---

284. The three appended tables have been prepared to show the kind of results which may be expected by treatment, in various ways, of strong, medium, and weak sewages. The figures, in the majority of cases, are averages from a fair number of samples, and where they are not based on actual observations, they have been arrived at from general experience.

It has been assumed that the sewage does not contain trade waste or any other substance in sufficient quantity to inhibit the action of the micro-organisms, that the works are efficiently managed, and that the filtering material used in the filters has a rough and vesicular surface.

The rates of treatment per cube yard of filter, or per acre of land, which are given are for the dry weather flow, but except in the cases noted on the tables, they are rates which can be doubled during storm times.

The actual size of plant, or area of land, which would be required in any case would depend on the extra amount of sewage which, in the particular case, had to be treated on land or on filters in wet weather.

As we shall subsequently explain,* we think that local conditions should determine what this extra amount should be.

The question of comparative cost of land treatment and artificial treatment has been dealt with in an earlier section of this Report, and also considerations arising out of the risk of nuisance from the different methods of treatment.

---

* *See* pp. 209 and 210.

TREATMENT OF STORM-WATER SEWAGE.

285. The proportion of rain-water from a drainage area which reaches the sewers and is conveyed to the outfall depends very largely on local circumstances, and consequently differs at different places.

Where, for example, the greater part of the drainage area consists of roofs and paved roads, the proportion of rain flowing off by the sewers will be greater than where the area chiefly consists of a more or less pervious soil.

Further, the amount of rain reaching the outfall will depend, to some extent, on whether the district is flat or hilly, the gradient of the main and tributory sewers, and what storm overflows are provided.

The system of sewerage will also make a considerable difference to the volume of liquid arriving at the outfall. Where a completely separate system of sewers for surface water exists, there will be only a small increase in volume due to rain ; with the partially separate system, there will be a considerable increase ; and with the combined system, a still greater increase.

286. At Hampton, which is provided with a separate system of sewers for surface water, we estimated the dry weather flow during the years 1902 and 1903 to be approximately 150,000 gallons per day, and the actual daily flow in all weathers to be about 165,000 gallons on the average—an increase due to rain of 10 per cent. only.

At Horfield, where the drainage area is sewered upon the partially separate system, but where there are no storm-overflows, gaugings over four months (April, May, June and July, 1905) showed the average daily flow to be approximately 62,350 gallons. As the dry weather flow was approximately 38,000 gallons per day, this represented an increase of 64 per cent. on the dry weather flow.

At Little Drayton, where the sewerage is on the combined system, and where there are two storm-overflows, one of which was temporarily dammed for the purposes of our observations, gaugings over three months (January, February and March, 1905) showed that the average daily flow was 15,350 gallons, or about 30 per cent. above the dry weather flow of 12,000 gallons.

At Rhyl, where the sewerage of the area is upon the combined system, and where there were no storm-overflows, gaugings made by Mr. Baldwin Latham for two entire years (1900–1901) gave the following figures. (Report* by Mr. Baldwin Latham to the Commission, June 29th, 1903, pp. 3 and 17) :—

Rainfall.	Number of days on which 0·01 inch or more rain fell.	Total flow in sewers.	Dry weather sewage flow, including subsoil water.	Water supply.	Rainfall flowing off (*i.e.*, increase in flow due to rain).	Rainfall and subsoil water.
Inches.		Gallons.	Gallons.	Gallons.	Gallons.	Gallons.
1900						
26·52	168	165,683,520	123,281,534	91,438,652	42,401,986	74,244,868
1901						
20·46	139	159,161,870	121,825,485	97,385,727	37,336,385	61,776,143

* Appendix V.

The increase of volume in this case, therefore, amounted to an average of 32·5 per cent. on the dry weather flow over the two years.

In his report, Mr. Baldwin Latham gives the following figures for Deal, which was also sewered on the combined system and had no storm-overflows:—

September, 1901, to February, 1903, inclusive.

Rainfall.	Number of days on which 0·01 inch or more rain fell.	Total flow in sewers.	Dry weather flow.	Rainfall flowing off.	Water supply to district.
Inches.		Gallons.	Gallons.	Gallons.	Gallons.
33·525	250	183,996,063	152,883,153	31,112,910	136,059,220

In this case, therefore, the increase was 20·35 per cent. on the dry weather flow.

At Rochdale, which is sewered upon the combined system, where the greater part of the area is paved or roofed, but where some thirteen storm-overflows exist, Mr. S. S. Platt, the Borough Surveyor, by gaugings extending over the year 1904, showed that the increase was roughly 52 per cent. of the mean dry weather flow.

At Oswestry, where the combined system is in use, but where the main storm-overflow is set rather low, Mr. G. W. Lacey, the Borough Surveyor, has found the increase to be about 21 per cent. of the mean dry weather flow. In this case a large quantity of subsoil water gains access to the sewers.

At Chorley, where the combined system is in use, where the main storm-overflow is set at about three times the mean dry weather flow, and where there are two local storm-overflows, the increase is about 45 per cent. In this case a small stream finds its way into the sewers.

In his report already mentioned, Mr. Baldwin Latham gives gaugings of the sewage flow at Croydon for the years 1880 to 1886 inclusive. The figures are summarised in Table 14, p. 28 of the report. From these figures, it will be seen that the increase of flow at that town due to rainfall was only 11·6 per cent. on the dry weather flow in the sewer, as calculated from the water supply. But it should be specially noted that in this case subsoil water is present in the sewers in the proportion of about 1·5 volumes to 1 of sewage, the consequence being that all variations of flow in the sewers are considerably levelled down.

Croydon is sewered upon the partially separate system, and there are no storm-overflows on the system.

287. While it is obvious from these few examples that the circumstances of different places vary considerably, the data available in regard to the effect of storms on the flow of sewage are exceedingly scanty.

In some few places records have been kept for a considerable period of the variation in flow in the outfall sewer and of the volume of sewage treated, but, so far as we are aware, there is little or no information available showing the volumes of liquid which have passed over storm overflows during the same period. It is, however, in some cases enough to do considerable damage to the river.

In the present state of knowledge, we consider that any regulations in regard to the amount of storm sewage to be treated and the method of treatment should be of a tentative character, and that, as regards storm overflows, each place must, to a great extent, be dealt with according to local circumstances. The general principle which should be followed is, we consider, that each local authority should so arrange its sewerage system as to prevent unpurified sewage from passing into the river or stream to an extent likely to cause nuisance.

288. As regards the effect of storms on the character of the sewage, the evidence which we have received, and also our own observations, show that, for the first hour or more, the effect of a storm is to increase the amount of organic matter in solution in the sewage as it arrives at the works, and also very largely to increase the suspended solids.

In our experience, the first flush of storm water contains a very large quantity of suspended matter washed out of the sewers, and is organically very impure. This flush, moreover, usually occurs at the time when the rainfall flowing off the area causes the maximum flow in the sewer, the consequence being that an ordinary storm-overflow on the sewers often has the effect of diverting to a water-course the worst part of the storm-water, while allowing the less foul storm sewage which arrives later to pass to the tanks or filters.

289. As a general rule, the difficulty of dealing with storm-water lies, not so much in the actual quantity flowing off an area as the result of rain, as in the rate at which it flows off. This is, of course, much more marked at some places than at others, the flow-off of rain-water being much more rapid when the greater part of the drainage area is more or less impervious, where the district is hilly, or where the sewers are laid upon a steep gradient. For instance:—

At Calverley—population 2,300—where the district is hilly, the main sewer steep, the sewerage system combined, and with rock immediately underlying the soil, as the result of a rainfall of 0·46″ falling in five showers on June 9th, 1902, the flow of sewage showed five sudden rises bringing the rates of flow up to 13, 32, 26, 29 and 30 times the mean dry weather flow. The total flow of sewage for the day, however, was only increased from the mean dry weather flow of 12,000 gallons to 43,700 gallons, or 3·64 times.

If a storm overflow had been set at Calverley to come into operation when the rate of flow was six times the mean dry weather flow, a large quantity of storm-water would have been discharged, untreated, on this day; whereas if a reserve empty tank, with a holding capacity of about 12,000 gallons, had been provided, and the overflow had been from this tank, the whole of the sewage and storm-water would have been treated; the beds receiving 3·64 times the normal quantity of sewage.

This is not an unusual occurrence at Calverley, and it has, moreover, been often observed there and at other places that the storm sewage is usually most foul when the storm flow is at its maximum rate.

On the other hand, if the district is flat, and especially if there is much leakage of subsoil water into the sewers, the flow of sewage will increase less rapidly as the result of rain, but continue swollen for some hours, or possibly some days. Halton, Oswestry, and Newton-le-Willows may be cited as illustrations.

290. In our opinion, the difficulties of dealing with the increase in flow, due to storms, can best be met by the provision of stand-by tanks to receive the storm sewage in excess of that which can be passed through the ordinary tanks. The main overflow at the works should be from the stand-by tanks, and not from the outfall sewer, so that no sewage may escape without some settlement.

The stand-by tanks should, of course, be kept empty as far as possible, so as to be at once available when a storm comes on.

We have not sufficient experience to enable us to suggest by what rules the capacity of the stand-by tanks should be determined, but we should think that tanks capable of holding a †quarter (six hours' flow) of the mean daily dry weather flow would usually be sufficient.

Local circumstances would, however, have to be considered in settling the capacity required for any particular place.

291. As illustrating the effect of stand-by tanks of the capacity suggested, we may give some figures taken from the report of Mr. Baldwin Latham, to which we have already referred.

At Friern Barnet sewage works, during nineteen wet days (average rainfall at the sewage works, 0·281″ per day), in August, September and October, 1887, instead of a total dry weather flow of sewage of 232,009 cubic feet, 515,793 cubic feet were found to arrive, 283,784 cubic feet being therefore due to rain. Of the total (515,793 cubic feet), 125,679 cubic feet, or 24·37 per cent., arrived at a rate in excess of three times the mean dry weather flow; 89,558 cubic feet, or 17·36 per cent., in excess of four times the mean dry weather flow; 67,412 cubic feet, or 13·07 per cent., in excess of five times the mean dry weather flow, and 50,015 cubic feet, or 9·7 per cent., in excess of six times the mean dry weather flow.

Assuming that all sewage up to three times the mean dry weather flow had been taken through the ordinary precipitation tanks, and that all flows in excess of this were directed into stand-by tanks of capacity 3,050 cubic feet (the dry weather flow at Friern Barnet was 12,211 cubic feet per day), then, out of a total of 515,793 cubic feet, 390,114 cubic feet (75·6 per cent.) would have been filtered in the ordinary way, and 125,679 cubic feet, or 24·37 per cent., would have received, before discharge into the water-course, the settlement shown in the following table :—

† Stand-by tanks are, we believe, giving excellent results at Colne, Lancashire, and also at Chorley. We understand the stand-by capacity at Colne is equal to about one-half the daily dry weather flow, and at Chorley to about one-third of the dry weather flow.

Date.	Number of hours the flow exceeded 3 times the mean dry weather flow (which was 12,211 cubic feet per day).	Volume of sewage in excess of 3 times the mean dry weather flow.	Settlement given in stand-by tanks.
1887.		Cubic feet.	
Aug. 16	5 hours	9,588	1 to 6 hours' continuous flow settlement after filling.
„ 17	1 hour	634	Quiescent settlement.
„ 20	1 hour	118	Quiescent settlement.
„ 26	3 hours	3,485	Mostly quiescent settlement.
„ 28	2 hours	1,243	Quiescent settlement.
„ 29	1 hour	1,492	Quiescent settlement.
„ 30	10 hours	16,620	1 to 6 hours' continuous flow settlement.
„ 31	8 hours	32,554	1 to 6 hours' continuous flow settlement.
Sept. 1	12 hours	11,909	1 to 6 hours' continuous flow settlement.
„ 2	3 hours	1,150	Quiescent settlement.
„ 3	6 hours	4,583	Quiescent settlement
„ 4	1 hour	118	Quiescent settlement.
„ 6	3 hours	6,341	1 to 6 hours' continuous flow settlement.
„ 7	9 hours	5,238	1 to 6 hours' continuous flow settlement.
„ 16	4 hours	5,246	1 to 6 hours' continuous flow settlement.
„ 17	9 hours	17,431	1 to 6 hours' continuous flow settlement
„ 26	3 hours	2,246	Quiescent settlement.
„ 30	3 hours	1,175	Quiescent settlement.
Oct. 10	5 hours	4,506	1 to 6 hours' continuous flow settlement.

The results obtained by Mr. Baldwin Latham at Croydon throughout the years 1880 to 1886 show that in a total number of 139 days upon which heavy rain fell (average rainfall per day 0·488″), out of a total of 73,768,896 cubic feet of sewage and rain-water flowing in the sewer, 12,201,773 cubic feet (or 16·2 per cent.) arrived at a rate in excess of three times the mean dry weather flow.

Taking the dry weather flow at Croydon to be 321,000 cubic feet, stand-by tanks of the capacity suggested would, in this case, have held 80,000 cubic feet, and, if the whole of the sewage and storm-water up to three times the dry weather flow had been passed through the ordinary tanks and plant, then 16·2 per cent. (12,201,773 cubic feet) of the total flow would have been sent into the stand-by tanks. Of the 139 wet days during the period stated, the total flow in excess of three times the dry weather flow only exceeded 80,000 cubic feet, or the assumed capacity of the stand-by tanks, on fifty-two days. In this case, of the total flow of 12,201,773 cubic feet, in excess of three times the dry weather flow, 7,696,935 cubic feet would have received quiescent settlement in the stand-by tanks and 4,504,838 cubic feet from one to six hours' continuous flow settlement, before discharge into the water course.

Mr. Latham's gaugings of the South Norwood sewage flow show that on fourteen wet days between January 13th and August 11th, 1866 (average rainfall per day 0·35″), out of a total flow of sewage and storm-water of 1,617,594 cubic feet, of which not less than 1,268,217 cubic feet were due to rain, 881,453 cubic feet (or 54·49 per cent.) arrived at a rate in excess of three times the dry weather flow.

In this case, the provision of stand-by tanks of the capacity suggested (six hours' flow) would have given quiescent settlement to 59,083 cubic feet out of the total flow of 881,453 cubic feet in excess of three times the dry weather flow, and one to six hours' continuous flow settlement to 822,370 cubic feet before discharge into the water-course.

It is to be observed from Mr. Baldwin Latham's report "that there were no storm-overflows in connection with the South Norwood sewers at the time the gaugings were made, and that, the district being of a more or less impermeable character, the volume of rain entering the sewers is very considerable, having regard to the extent of the district and the population draining to the sewers."

We are greatly indebted to Mr. Baldwin Latham for the Report which he kindly made to us on the subject of the increase in the flow of sewers caused by storms. This Report is published in Appendix V.

Storm Water Filters.

292. Speaking generally, we are not in favour of special storm-water filters, for although, if well constructed and scientifically managed (*e.g.*, as at Manchester), they can be made to give good results, our experience has led us to the conclusion that—as generally constructed and used—they do not effect a purification in proportion to their cost.

If storm-water filters are not regularly used, their oxidising efficiency may, in times of dry weather, become impaired. If, therefore, they are to be used in dry weather, in order that they may be kept mature, it appears to us that they should be as well and as carefully constructed as the ordinary filters. It seems also false economy to have some part of the filtering area out of use for any length of time when the additional area, if used, would be of advantage in giving regular periods of rest to sections of the normal filtering area.

Amount to be filtered.

293. We think it may be taken that it is practicable to filter three times the mean dry weather flow, and while there are few or no data to show that this is the right amount for which filtration is required, we doubt whether, as a general rule, the filtration of any larger amount will be found to be necessary to prevent nuisance.

Assuming, that three times the dry weather flow had to be filtered, we consider that it would only be necessary to provide at a works $1\frac{1}{2}$ times the area of filter which would be necessary if only the dry weather flow had to be treated; this area would, in our opinion, allow of the filtration of three times the mean dry weather flow, as the filters can be worked at an increased rate during storms.

Recommendation.

(a) *Overflows on Branch Sewers.*

294. It is probably impracticable to dispense altogether with storm overflows on branch sewers, but in our opinion these should be used sparingly, and should usually be set so as not to come into operation until the flow in the branch sewer is several times the maximum normal dry weather flow in the sewer.

No general rule can be laid down as to the increase in flow which should occur in the branch sewers before sewage is allowed to pass away by the overflow untreated. The Rivers Board, or in districts where there is no Rivers Board, the County Council, should have power to require the local authority to alter any storm overflows which, in their opinion, permit of an excessive amount of unpurified sewage to flow over them. The local authority should have the right to appeal to the Central Authority in any case in which they consider that the requirement of the Rivers Board is unreasonable or impracticable of fulfilment.

The general principle should be to prevent such an amount of unpurified sewage from passing over the overflow as would cause nuisance.

(b) *Treatment of Storm Water Sewage at the Works.*

295. The usual requirements of the Local Government Board in regard to the treatment of storm sewage are that any increase in flow up to three times the normal dry weather rate should be fully dealt with by the ordinary complete plant, and that a certain number of additional dilutions—up to a total of six—should be treated on special storm filters. These requirements should, we think, be modified: they are, in our opinion, not sufficiently elastic; and, moreover, experience has shown that special storm filters, which are kept as stand-by filters, are not efficient. We find that the injury done to rivers by the discharge into them of large volumes of storm sewage chiefly arises from the excessive amount of suspended solids which such sewage contains, and that these solids can be very rapidly removed by settlement. We therefore recommend, as a general rule—

(1) That special stand-by tanks (two or more), should be provided at the works and kept empty for the purpose of receiving the excess of storm water which cannot properly be passed through the ordinary tanks. As regards the amount which may be properly passed through the ordinary tanks, our experience shows that in storm times the rate of flow through these tanks may usually be increased up to about three times the normal dry weather rate without serious disadvantage;

(2) That any overflow at the works should only be made from these special tanks, and that this overflow should be arranged so that it will not come into operation until the tanks are full;

(3) That no special storm filters should be provided, but that the ordinary filters should be enlarged to the extent necessary to provide for the filtration of the whole of the sewage, which, according to the circumstances of the particular place, requires treatment by filters.

(4) As regards the overflow from the outfall sewer to the stand-by tanks, the size of the stand-by tanks, the amount of storm sewage which should be filtered, and the arrangements generally for dealing with storm sewage at the outfall works, the Rivers Board, or the County Council in areas in which no Rivers Boards have been established, should have similar power to that which we have proposed in regard to overflows on branch sewers, and the Local Authority should have a similar right of appeal to the Central Authority.

SEPARATE AND COMBINED SYSTEMS OF SEWERS.

296. In recent years there has been a tendency to favour the adoption of separate sewers to carry what is called surface water, and some local authorities have obtained, by means of local acts, special powers enabling them to call upon frontagers in private streets to lay down two sewers instead of one.

In the Public Health Bill of last session (1907) a clause, dealing with this subject, was originally included, but it was omitted during the passage of the Bill through Parliament.

In our opinion the cases in which the provision of a separate system can properly be justified are rare, and it appears to us that the relative merits of the separate and combined systems have not always been sufficiently considered.

It is obvious that the provision of two systems of sewers and two sets of house drains would very largely increase the initial outlay on drainage works, the exact amount of the increase depending on local circumstances.

It seems generally to have been assumed by advocates of the separate system that the liquid brought down by surface water sewers is sufficiently pure to need no purification, and further, that by excluding this water from the ordinary sewers a much smaller area of land or filters, as the case may be, will suffice for the purification of the sewage.

Neither of these assumptions is altogether justified.

297. As regards the quality of the liquids which are discharged from surface-water sewers, we may refer to the following analyses which we have made :—

Chemical Analyses.

	Rugby.	Aldershot Camp.		South Norwood.

188B. S. Norwood. Street "Washings" after running 4 hours. 1/12/00.†	9,900,000	380,000	1,000 (Indol + ·001 c.c.) + ·1, – ·01 c.c. "gas" in gelatine shake cultures.	+ ·01, – ·001 c.c. At least 100 but less than 1,000.

* Two guinea-pigs (a and b) were subcutaneously inoculated with 1 c.c. (a) and 2 c.c. (b) of sample 96A (street washings). Both showed a strong local reaction; (a) guinea-pig recovered, but (b) guinea-pig suffered from ulceration of the abdominal wall and died on the fourth day.

† Two guinea-pigs (a, b) were subcutaneously inoculated with 1 c.c. (a) and 2 c.c. (b) of sample 188B; (a) guinea-pig developed a big swelling at the site of the inoculation, but eventually recovered completely; (b) guinea-pig died on the second day.

§ A guinea-pig was subcutaneously inoculated with 4 c.c. of sample 231 (street washings). It died on the second day, doubtless from the effects of the injection.

The chemical analyses of these samples may be shortly summarised as follows :—

No. 231, street "washings" taken from a surface-water drain at Rugby on March 4th, 1901, at a time when the street was very clean after heavy showers, was turbid and brown with a large amount of gritty sediment, but comparatively pure as regards organic matter; it withstood incubation.

No. 311, street "washings" from a surface-water ditch at Aldershot, was drawn on the 2nd July, 1901, after two days' heavy rainfall; at the time of drawing, the water in this ditch was flowing at about the rate of ten million gallons per 24 hours. The above sample was brown and turbid (though it had only a slight brown tinge when filtered), and it contained a great deal of sand and also brownish suspended matter. The analyses gave the high figure of 0·49 parts Albuminoid Nitrogen, 1·05 Total Organic Nitrogen, and 8·93 "Oxygen absorbed" in four hours. Though this had a clean smell when analysed, it became black and putrid on incubation.

No. 314, street "washings" and roof water from Aldershot Camp, drawn July 3rd, 1901, after three days' rain, was muddy from a considerable quantity of suspended solids with grit in addition. Though the aggregate organic matter was less than in sample No. 311 (the figures being 0·34 Albuminoid Nitrogen, 0·64 Total Organic Nitrogen, and 3·46 "Oxygen absorbed"), it was smelling slightly when analysed and became black and putrid on incubation.

No. 174, drawn November 14th, 1900, was a sample of surface water from streets and front roofs drawn at South Norwood during sharp showers, the weather having been showery on the day previous. It contained a good deal of sand, but was comparatively pure as regards organic matter and kept good upon incubation.

No. 179, drawn November 21st, 1900, was another sample of surface water from the South Norwood streets, after moderate showers, the streets having been previously washed fairly clean by rain. This did not contain much sediment, but was organically more impure than the preceding sample; it had no smell when received, but became putrid upon incubation.

No. 182 was drawn on November 28th, 1900, at South Norwood, after the surface drain had been running for three hours. It was very turbid and brown and contained much grit. Organically, it might be classed as a dilute sewage.

No. 187a, South Norwood street water, drawn December 1st, 1900, after a slight rainfall, was comparatively pure as regards organic matter. Though it showed a good deal of flocculent sediment, it kept sweet upon incubation.

Three out of these seven samples were therefore non-putrescible; but the other four were undoubtedly polluting liquids.

Bacteriologically, all the samples may be classed as bad.

Although the above samples were few in number, they show (1) that even when a street water is comparatively pure organically, it requires settlement for grit (Nos. 174 and 231); and (2) that even after long-continued rain, street surface waters may be very impure (Nos. 182, 311 and 314).

Valentine, 22407. Wilkinson, 22603. Wike, 23515. Reid, 20730–1.

298. The witnesses who have given evidence on this question have agreed that the first flush of water from a surface-water system during a storm is of such a foul nature that it ought to be purified, if practicable, especially if the system brings water from paved open spaces such as markets, squares, etc.

Messrs. G. H. Pickles and Raymond Ross gave the following analysis of a typical sample of surface water from a surface-water drain at Burnley, taken during the early period of a storm :—

	Parts per 100,000.
Free Ammonia	·8
Albuminoid Ammonia	·2
Chlorine	4·0
Oxygen absorbed	5·3
Total solids	71·2
Suspended matter	44·0

They stated, also, that this sample contained about 800,000 bacteria per c.c. as shown by gelatine plate cultivation at 23°C.

Mr. Bolton, in his evidence relating to Heywood, gives the following analysis of a sample of road water, taken in the principal streets during the first rushes of storm surface water :— 21096.

	Parts per 100,000.
Ammoniacal Nitrogen	1·11
Albuminoid Nitrogen	·49
Oxygen absorbed in 3 minutes	12·5
Oxygen absorbed in 4 hours	19·9
Chlorine	8·7
Solids in suspension	84 { vol. 25 / non vol. 59
Solids in solution	73 { vol. 22 / non vol. 51
Total solids	157

299. Experience also shews that with two sets of drains to each house there is danger of the sewage drain being connected with the surface-water sewer, and in densely populated areas, slops and other filthy liquids are often emptied into street gullies, and pass directly into the surface-water sewer.

There can be no doubt, therefore, that the liquid brought down by surface-water sewers is frequently of a polluting nature, and that, in many cases, it might be necessary to provide for its treatment.

---

300. As to the other assumption, that by keeping surface water out of the sewers the area of filters or land necessary for purification may be materially reduced, we may refer to the experiments which we carried out at Accrington, in regard to the filtration of diluted and undiluted septic tank liquor (see pages 16 and 110 *et seq.*).

These experiments shewed that, within ordinary limits of concentration and volumes treated, the amount and nature of the organic impurity present mainly determine, in practice, the ease or difficulty of purification; in other words, that, within limits, mere dilution does not affect the size of the filtering plant which is necessary. Of course, if the dilution is so great as to cause water-logging of the filters, their purifying power would be seriously diminished, and this statement would not hold good.

We may also observe that the flushing of sewers by rain water, which occurs with the combined system, is in itself useful, and that there is some evidence to show that filters work better when storm sewage, from which the solids have been settled, is occasionally passed through them.

24260, Fowler. 22745, Watson. 24955, Wilkinson.

301. As regards the cases in which the adoption of a separate system for surface water may be allowed, we may refer to the evidence of Dr. Fowler, Mr. Watson, and Mr. Wilkinson. These gentlemen have had considerable experience, and they expressed the view that in large towns the separate system is impracticable, that in urban districts a combined system is justified on sanitary and economical grounds, and that only in villages, country districts, and suburban areas, where there is little traffic and where the surface water will not be very foul, may the separate system sometimes be adopted with advantage.

With these views we generally concur, and we think it would be unwise to confer on all local authorities power to enforce the adoption of the separate system of sewerage, and the provision of two sets of drains in every house.

In our opinion this power should not be conferred on any local authority until the local circumstances have been carefully considered by some independent tribunal.

Recommendation.

302. We recommend that in any case in which a local authority wishes to adopt the separate system of drainage for the whole or any part of their district, they should be required to apply to the Central Authority, and that the Central Authority should be empowered to confer on the local authority, by order, such powers as may be deemed necessary.

As regards the powers which may be necessary, we may observe that the provisions which are generally contained in local Acts in regard to this matter seem to be defective. If separate sewers are provided, the local authority should have a clear power to enforce the provision of separate drains, but the local Acts to which our attention has been drawn do not modify the powers of the local authority under the general law in regard to bye-laws as to the drainage of houses.

Moreover, the powers of the local authority in this connection should not necessarily be limited to new streets and new houses.

As a general rule, the expense of altering existing drains should fall on the local authority, and there may be some instances in which it would be equitable that they should bear some portion of the additional cost even in the case of drains being constructed for the first time.

The Central Authority should therefore have power to include in their Order such provisions for the allocation of the cost as they consider equitable, having regard to the local circumstances.

PART VI.—STANDARDS FOR SEWAGE EFFLUENTS.

303. A number of chemists and others were kind enough to furnish us with their views on the question of standards, in response to a circular letter which we issued in May, 1903. This letter and the replies are printed in Appendix VII.

We have also examined several witnesses on this subject, and have ourselves made some experimental investigations.

The harm caused by allowing unpurified, or imperfectly purified, sewage to flow into rivers and streams may be placed under one or more of the following headings:—The de-aeration of the water of the river, and consequent injury to fish; the putrefaction of organic matter in the river to such an extent as to cause nuisance; the production of sewage fungus and other objectionable growths; the deposition of suspended matter, and its accumulation in the river bed or behind weirs; the discharge into the river of substances, in solution or suspension, which are poisonous to fish or to live stock drinking from the stream; the discoloration of the river; and the discharge into the river of micro-organisms of intestinal derivation, some of which are of a kind liable, under certain circumstances, to give rise to disease.

304. We observe that previous Commissions have reported that, of all the processes which were proposed for the purification of sewage, or of water polluted by excrementitious matter, there is not one which is sufficiently effective to warrant the use, for dietetic purposes, of water which has been so contaminated, and the 1868 Commission stated that, in their opinion, "rivers which had received sewage, even if that sewage had been purified before its discharge, were not safe sources of potable water." We, therefore, conclude that the framers of the Rivers Pollution Prevention Act, 1876, did not contemplate that local authorities should be required so to deal with their sewage that the rivers into which the purified sewage flowed might be regarded as safe sources of water supply, in cases in which the water was not to be filtered before distribution.

305. In our opinion much the same position must be taken up to-day. Although the methods available for the purification of sewage are more numerous than when the 1868 Commission reported, our examination of a very large number of effluents from sewage farms, and from artificial filters of various kinds, shows that, although such effluents may be very good as judged by chemical and physical tests, they are generally liable to contain large numbers of micro-organisms of intestinal derivation, and that if such organisms are to be destroyed, or eliminated, the effluents must be subjected to some treatment additional to that which is ordinarily employed.

We have carried out some experiments for the purpose of ascertaining the practicability of certain of the methods which have been suggested for the removal or destruction of these micro-organisms. These experiments, which are described in Dr. Houston's Report, Appendix IV., have shown that, while it would be practicable to render sewage effluents fairly pure, bacteriologically, the cost of the necessary additional treatment would be serious.

306. Moreover, a false sense of security would be obtained by the adoption of such further treatment unless, at the same time, storm overflows on sewers were abolished.

In the great majority of towns, sewers are provided with storm overflows, by which, in times of storm, large quantities of sewage are discharged into the river or stream untreated. Such discharges, we find, are frequently more impure, bacteriologically, than the normal crude sewage.

In the opinion of some engineering witnesses whom we have called before us, it would generally be impracticable to dispense with storm overflows, but assuming, as an engineering possibility, that they could generally be dispensed with, it is quite clear that the necessary enlargement of the sewers would involve a very large outlay. In some towns, if there were no storm overflows, the effect of a storm would be to cause the flow in the sewers to be very many times the normal rate for a short period.

307. By constructing a separate system of sewers for storm water the effect of storms on the other sewers would no doubt be greatly lessened, but if bacterial purity is to be required in the case of all discharges from sewers, it would be necessary to provide a second plant for the treatment of the liquids flowing in the storm water sewers, as these liquids are often exceedingly impure.

The amount of liquid which would be brought down by such separate sewers would vary, according to local conditions, but during the course of a year it would probably be at least half as much as the volume carried by the other set of sewers.

308. In our opinion, the cost of reconstructing the sewers so as to allow of the abolition of storm overflows, together with the cost of providing and maintaining purification plant which could be relied on at all times to render the total refuse waters of a town both chemically and bacteriologically pure, would in most cases be practically prohibitive; and further, even if this additional burden were placed on local authorities, the water of rivers would generally still require to be treated before it could be safely distributed for drinking purposes.

309. We are satisfied that rivers generally, those traversing agricultural as well as those draining manufacturing or urban areas, are necessarily exposed to other pollutions besides sewage, and it appears to us, therefore, that any authority taking water from such rivers for the purpose of water supply must be held to be aware of the risks to which the water is exposed, and that it should be regarded as part of the duty of that authority, systematically and thoroughly, to purify the water before distributing it to their customers.

310. Apart from the question of drinking waters, we find no evidence to show that the mere presence of organisms of a noxious character in a river constitutes a danger to public health or destroys the amenities of the river. Generally speaking, therefore, we do not consider that in the present state of knowledge, we should be justified in recommending that it should be the duty of a local authority to treat its sewage so that it should be bacteriologically pure.

311. The evidence adduced before us and the results of our own investigations show that the extent to which the purification of a sewage need be carried in order that none of the other injuries mentioned in paragraph 303 shall be done to the river into which it is discharged varies with the particular circumstances of the town and river concerned.

The statute law, however, recognises no graduated standards of purity for sewage effluents.

Under the Rivers Pollution Prevention Act, 1876, in the case of sewage entering non-tidal waters, the duty is imposed on the local authority of adopting the best practical and available means to render the sewage harmless before it enters the river, and no local circumstances may be taken into account. The effluent by itself is alone to be considered.

312. We fully realise that from the point of view of administration it is simpler to regard the effluent alone, and also that it has not been usual for County Councils, Rivers Boards, or others, to press the provisions of the Act of 1876 unduly. Our terms of reference require us, however, to have regard to the "*economical* and efficient" discharge of the duties of local authorities, and in view of the importance of not requiring a local authority to incur any further expenditure on sewage disposal than the circumstances of its area require, we feel strongly that the law should be altered so as to allow local circumstances to be taken into account.

Suspended Solids in Effluents.

313. One point in regard to which we think that strict regulations will usually be found necessary is the reduction of the suspended solids of an effluent to a low figure, before that effluent is allowed to escape into a watercourse. As is well known, these suspended

solids are always—or practically always—putrescible. Indeed, we cannot recall any instance in our own experience in which such solids, when examined apart from the liquid portion of the effluent, were non-putrescible.

Our observations show that the volatile matter of the suspended solids in effluents from artificial filtration may be taken, on a rough average, as constituting about two-thirds of the whole, the remaining one-third being mineral matter. Although it is not strictly correct to say that this "volatile" matter is all organic, we think that it may be considered so for practical purposes.

A description, by Messrs. O'Shaughnessy and Kinnersley, of the suspended solids washed out in the effluent from one of the Birmingham percolating filters is to be found in the *Journal of the Society of Chemical Industry* for 1906. They found them to consist of a very complex mixture of structureless matter, dead organisms undergoing disintegration, zooglea, mineral matter, etc.

A large number of specific instances are given, in the *reports on the various sewage works which have been under observation for the Commission, of the rates at which such solids take up dissolved oxygen from water.

The results show that the suspended solids from biological sewage filters, whether contact beds or percolating filters, are in themselves putrescible, and that they are capable of taking up oxygen from water comparatively rapidly. So long as such solids are kept moving in oxygenated water, or in water containing nitrate in solution, they will not give rise to nuisance from smell, but if allowed to accumulate in the sluggish reaches of a stream, they will ultimately form black and putrid mud, which will draw upon the oxygen in the supernatant water ; if present in very large quantity, they will, in those circumstances, give rise to objectionable conditions.

314. Our own experience, and also the evidence which we have received, leads us to attach much importance to the prevention of a large amount of suspended solids being discharged into most rivers and streams, and our observations show that it is quite practicable to produce effluents fairly free from suspended solids.

The following places, among others, where various systems of treatment are followed, may be cited as giving a general effluent containing at most 3 parts of suspended matter per 100,000 :—

Birmingham.	Friern Barnet.	Royton.
Burnley.	Guildford.	Salford.
Carshalton.	Hampton.	Salisbury.
Caterham.	Hendon.	Staines.
Chesterfield.	Heywood.	St. Albans.
Chorley.	Kingston.	Shipley.
Clifton.	Newcastle-under-Lyme.	Wednesbury.
Darwen.	Oswestry.	Withington.
Dorking.	Prestolee.	Withnell.
Exeter	Radcliffe.	

As a general rule, we consider that the harm due to suspended solids would not be serious, if the effluents contained not more than 3 parts of suspended solids† per 100,000, and it is shown by experience that this would not be an unreasonable figure to demand in the majority of cases. There are, of course, cases where a larger quantity of solids might be safely allowed in an effluent, while in some others even 3 parts might be too much.

Other Qualities of Effluents.

315. We shall discuss in the next section of this report various tests for sewage effluents, but we may at once state that we doubt whether the figures obtained in the laboratory have, in the past, been sufficiently considered in connection with observed conditions of the stream to justify positive inferences being drawn from such figures as to the effect of effluents on streams.

* See Appendix III. † This is equivalent, as a rule, to about 2 parts of organic matter in suspension.

In connection with an investigation which we are making in regard to the disposal of distillery waste liquids, we have constructed a number of artificial streams. We find that effluents which are derived from strong original liquids may often contain large amounts of organic matter in solution, and yet not take up dissolved oxygen rapidly from water, or cause injury to streams into which they are discharged. If these observations had not been made such effluents, judged by the empirical tests in common use, might have been regarded as polluting liquids.

These observations, together with other experiments and the work done by others, show that the effect of an effluent on a stream does not generally depend on the absolute amount of organic matter contained in it, but rather on the nature and condition of that organic matter, and that the important thing to ascertain in examining an effluent, is the extent to which the original organic matter has undergone fermentation.

We are extending this method of observation to a variety of streams and effluents, and in our final report we hope to be able to indicate, by reference to figures obtained in the laboratory, a range of standards of varying degrees of stringency.

Recommendation.

316. We recommend that the Central Authority should determine the nature of the tests which are to be applied for the purpose of standards, and that it should be made the duty of the Rivers Board, or of the County Council, in areas not under the jurisdiction of a Rivers Board, to determine from time to time, subject to appeal to the Central Authority, what standards should be adopted.

317. In the first instance it would be convenient that the Central Authority should prescribe one standard for all non-tidal waters, in place of the existing statutory provisions. It would then rest with the Rivers Board or County Council to fix, subject to appeal to the Central Authority, a higher or lower standard, in any case in which they were of opinion that the circumstances required or justified a different standard.

318. We further recommend that no action should be allowed to be brought in respect of damage alleged to be due to the discharge of an effluent which complies with the standard fixed for the water into which it is discharged, but that in such cases complaint should be made to the Central Authority, and, if a *prima facie* case is made out, that Authority should ascertain whether the complaint is well founded and should be empowered to fix a different standard if the circumstances are shown to require it.

In cases where it is alleged that the effluent does not comply with the statutory standard, and that damage is caused by the discharge of such effluent, action should be brought in the ordinary courts.

But any questions arising as to whether the effluent complies with the statutory standard or as to whether the damage has been caused by the discharge of the effluent in respect of which complaint is made, should be referred by the Court to the Central Authority for determination. The costs of such determination should be borne by the parties to the action in such proportions as the Court may determine.

319. Power should be conferred on the Central Authority to suspend from time to time the operation of any standard, to allow time for the construction of works, or for any other reason which, in their opinion, justified such suspension.

TESTS FOR SEWAGE EFFLUENTS IN RELATION TO STANDARDS.

320. The experiments which we have already made show that the mere estimation of the amount of organic matter in an effluent does not, by itself, afford a sufficiently reliable index as to the effect which that effluent will have on any stream into which it may be discharged.

Effluents which are derived from strong sewages may contain comparatively large amounts of organic matters, and yet not take up oxygen rapidly from water or cause any serious growth of sewage fungi in streams, while effluents derived from weak sewages, although containing smaller amounts of organic matters, may take up oxygen comparatively rapidly and foul a stream into which they are discharged.

The primary object of applying tests to a sewage effluent should be to ascertain whether the effluent may be discharged into a stream without giving rise to effects such as these, and we are extending our observations on streams with a view to ascertaining the value of various tests from this point of view.

Until these observations are completed we do not propose to report finally on the question of tests and standards. We can, however, at once state that any figures of analysis, unless they bear a direct relation to the state of the effluent as regards fermentative change, may be misleading.

321. According to our present knowledge, an effluent can best be judged by ascertaining, first, the amount of suspended solids which it contains, and, second, the rate at which the effluent, after the removal of the suspended solids, takes up oxygen from water.

In applying this test it is important that the suspended solids should be removed, and estimated separately.

Small variations in the amount of suspended solids in effluents may seriously affect the rate at which the effluents take up oxygen, and unless these solids are first removed, the dissolved oxygen absorption test might give a misleading figure as to the character of the effluent.

322. For the guidance of local authorities we may provisionally state that an effluent would generally be satisfactory if it complied with the following conditions :—

(1) That it should not contain more than 3 parts per 100,000 of suspended matter ; and

(2) That, after being filtered through filter paper, it should not absorb more than :

(*a*) 0·5 part by weight per 100,000 of dissolved or atmospheric oxygen in 24 hours ;

(*b*) 1·0 part by weight per 100,000 of dissolved or atmospheric oxygen in 48 hours ; or

(*c*) 1·5 parts by weight per 100,000 of dissolved or atmospheric oxygen in 5 days.

At many sewage works which we have had under observation effluents of this class are uniformly produced.

As regards the carrying out of the dissolved oxygen test, or aeration test as it is sometimes called, we may refer to page 15 of this Report, which deals with the test in relation to sewage, and also to pages 96 and 438 of Appendix VI.

Growths in Streams.

323. The question of growths in streams is one of some importance and difficulty.

Even the best effluents contain a certain amount of plant food in solution and therefore tend to promote vegetable growths. In the case of a stream receiving well purified and nitrated effluents, these growths are green. If, however, green growths form in quan-

tity, and become detached and washed down into stagnant pools, they must ultimately undergo decomposition and may possibly give rise to nuisance.

This aspect of the question is being further studied ; but we may remark that it does not seem practicable to purify sewage thoroughly without the production of nitrates which remain in the effluent, and tend to promote growths.

In the case of a stream receiving imperfectly purified effluents, grey growths (leptomitus, sphaerotilus, etc.) may be fostered. These not only give a stream an unpleasant appearance, and tend to choke its bed, but when washed down and allowed to accumulate, may become very offensive, especially in warm weather. So far as our observations have gone, such growths flourish best in a mixture consisting partly of unpurified sewage liquor and partly of oxygenated and nitrated water or effluent.

This is illustrated by some channel experiments at Chorley, which we began towards the end of February, 1907. One of the channels carried a mixture of 75 volumes of filter effluent and 25 volumes of well-clarified precipitation tank liquor. The mixture gave the following average figures of analysis :—

Parts per 100,000.	Average.	Number of Estimations.
Ammoniacal nitrogen (1·34 to 3·6)	2·2	4
Albuminoid nitrogen (0·14 to 0·20)	0·16	3
Oxidized nitrogen (1·76 to 2·32)	2·2	3
"Oxygen absorbed" in 4 hours (0·81 to 2·21)	1·4	6
Dissolved oxygen taken up from water *in 5 to 8 days* (0·65 to 2·81)	1·4	6
Dissolved oxygen taken up from water *in 24 hours* (0·18 to 1·16)	0·8	3
Incubator test (by smell)	All passed.	6

In spite of these comparatively good figures, and the fact of the liquid being non-putrescent upon incubation, the channel was, in June, 1907, filled from end to end with a thick grey fungoid growth.

Another channel, conveying purified filter effluent, had only a green growth, coated to some extent with effluent solids, while a third channel which carried filter effluent plus a proportion of storm water equivalent, *on the average*, to 30 per cent. of the total volume of liquid delivered to the channel, became full of black putrescent mud, but had little or no sewage fungus.

We are not at present in a position to state with certainty, by reference to figures of analysis, what effluents will, and what effluents will not, cause objectionable growths in streams.

Nitrates in Effluents.

324. Although a well nitrated effluent usually takes up dissolved oxygen from water slowly, this is not always the case. The following effluent (from a strongly ammoniacal sewage) is an instance of this variation :—

	Parts per 100,000.
Ammoniacal nitrogen	13·02
Albuminoid nitrogen	0·48
Nitrous nitrogen	0·26
Nitric nitrogen	4·70
Solids in suspension	Trace.
"Oxygen absorbed" at 27° C. (80° F.) *at once*	1·96
"Oxygen absorbed" at 27° C. (80° F.) in 4 hours	5·62
Dissolved oxygen taken up from water at 18°C. (65°F.)	
(*a*) in 24 hours	0·89
(*b*) in 48 hours	2·16
Incubator test (by smell)	Passed.

Here, although there are about five parts of oxidised nitrogen present in the liquid, there still remains a considerable quantity of readily oxidizable organic matter. Conversely, instances might be given of effluents, poor in nitrate, which took up very little dissolved oxygen from water.

Chemical Poisons in Effluents.

325. We have not yet studied this point in much detail, but we think that very few effluents in which the organic matter had been well oxidized, would contain chemical poisons in quantity sufficient to do harm to fish life, and that the heavy metals would be brought down in the sludge. When the Leeds sewage was known to contain a considerable quantity of arsenic, the effluents from its biological filtration showed only minute traces of it.

Cases may occur where chlorine compounds, acids, or alkalies, might be present in an effluent. We have heard, for instance, of the addition of lime, for the purpose of temporarily sterilizing a poor effluent; such effluents would of course be detrimental to fish.

The Relation of certain Tests to One Another

326. Dr. McGowan has made a careful comparison of the figures of analysis of 163 effluents of varying degrees of purity and obtained by various artificial processes. In most of the cases a determination was made of the dissolved oxygen taken up by the effluent from water in twenty-four hours, as well as of the "oxygen absorbed" from permanganate, etc.

As a result of this comparison we find that:—

(1) The figures for albuminoid nitrogen and for "oxygen absorbed" from (strong) permanganate in four hours show a close parallelism, but bear no constant ratio to one another. In well, or fairly well, purified effluents, comparatively free from suspended solids, the ratio will usually be something like one part of albuminoid nitrogen to ten parts of "oxygen absorbed" in four hours at 27° C. (80° F.).

(2) The ratio of albuminoid to total organic nitrogen in an effluent is usually from 1 : 2 to 1 : 3, though it may in certain cases be either below or above those figures. When an effluent contains a large quantity of suspended solids, the ratio tends to be high.

(3) There is nothing like a definite ratio between the figures for albuminoid (or total organic) nitrogen and ammoniacal nitrogen in an effluent. The actual quantity of free ammonia left in an effluent, especially if it be compared with that in the original sewage or tank liquor, furnishes, however, a very valuable indication of the extent to which oxidation has been promoted by the filter.

(4) The ratio of "oxygen absorbed" at once from (strong) permanganate to "oxygen absorbed" in four hours is usually fairly constant at about 1 : 3 to 1 : 4, though there are a good many exceptions.

The main object of the test—"oxygen absorbed" at once (or in three minutes)—is to show whether there is an abnormal quantity of quickly oxidisable matter, whether organic or inorganic, in a sewage liquid. It cannot be regarded as a substitute for the four hours test.

(5) The ratio of dissolved oxygen taken up from water in twenty-four hours at 18° C. (65° F.) to "oxygen absorbed" from permanganate in four hours at 27° C. (80° F.) shows very wide variations, and the figures cannot be said to bear much relation to one another, except in a very general way. When the ratio is low, the effluent is more often than not of poor quality. With a high ratio —say, over 1 : 5—the effluent is almost always a good one.

(6) The ratio of dissolved oxygen taken up in *twenty-four hours* to "oxygen absorbed" from permanganate *at once* varies very much also; as a general rule the better effluents show the higher ratios.

The Relation between the Incubator or Non-putrescibility Test and the taking up of Dissolved Oxygen from Water.

327. There is no certain correspondence between the results of these two tests. An artificial effluent, made by adding excess of nitrate to a diluted sewage, takes up dissolved oxygen at a rapid rate, but the nitrate prevents it from putrefying upon incubation.

At the same time we find that when an effluent is pretty well purified, there is fairly definite relationship between the two tests.

Of the 163 effluents of varying degrees of purity which were examined by Dr. McGowan, 107 did not putrefy on incubation ; forty-nine putrified ; and seven were doubtful.

Of the 107 effluents which did not putrefy on incubation, ninety-eight were tested for dissolved oxygen absorption, and were found to take up an average of 0·57 part per 100,000 in 24 hours. The figures ranged from 0·0 to 3·2 parts per 100,000, and in most of the cases where a high figure was obtained, there was much suspended solid in the effluent. There were thirty-five effluents which contained over 3 parts of suspended solids per 100,000 (the average being 7·1 parts), and these took up an average of 0·85 part of dissolved oxygen in 24 hours. The remaining sixty-three effluents, which contained 3 parts or less of suspended solids per 100,000, took up an average of 0·41 parts of dissolved oxygen. Again, of nineteen of the effluents which did not putrefy on incubation, but which seemed of somewhat indifferent quality as judged by the figures of analysis, only five took up more than 1 part of dissolved oxygen.

Of the forty-nine effluents which putrefied on incubation, thirty-three were tested for dissolved oxygen absorption, and were found to take up from 0·57 to 7·0 parts (or an average of 2·3 parts) of oxygen from water in 24 hours.

We may summarise the position as follows :—

(1) It is very rare indeed for an effluent which (apart from suspended solids) takes up little dissolved oxygen from water to fail upon incubation.

(2) It is comparatively infrequent for an effluent (apart from suspended solids) which withstands incubation to take up dissolved oxygen from water at a rapid rate.

(3) In the great majority of cases an effluent which fails to withstand the incubator test will also take up much dissolved oxygen from water ; and

(4) An effluent which takes up much dissolved oxygen from water will also usually fail upon incubation.

Both these tests depend upon the fermentative changes which may take place in an effluent, on keeping, but a standard based upon a low figure of dissolved oxygen absorption would, in some cases, be more stringent than a standard of non-putrescibility alone.

328. It is, we think, probable that an effluent which does not take up dissolved oxygen from the water of a stream more rapidly than that water can naturally re-aerate itself from the air, would neither give rise to unpleasantness nor—assuming the absence of chemical poisons—injure fish life, but this is a point on which we shall be able to speak more definitely after the conclusion of our observations on streams.

* *Condition of Effluent as regards Aeration.*

329. In some circumstances the question of the amount of dissolved oxygen contained in the effluent would be of importance. If the effluent were almost completely de-aerated, as many contact bed effluents are, and were to be discharged into a stream, the volume of which was small as compared with the volume of effluent, the mere admixture of stream and effluent would, at all events near the point of discharge, produce a liquid in which the amount of dissolved oxygen would be far below the saturation point.

It should be added that it would probably not be difficult to aerate a contact bed effluent previous to its discharge into the stream.

Effluents from percolating filters are usually well aerated.

---

* See also Report by Dr. Letts and Dr. Adeney. Appendix VI.

PART VII.—POLLUTION OF ESTUARIES AND TIDAL WATERS.

330. In our fourth report we dealt with the question of the pollution of tidal waters, with special reference to contamination of shell-fish.

As regards the standard of effluent that can be permitted for tidal waters, having regard to the reasonable protection of salmon fisheries and the avoidance of nuisance, we stated that we did not think it practicable to lay down any fixed rules, as the necessities of each case would depend on a variety of considerations. We were, however, of opinion that in certain circumstances sewage should be purified before it is discharged into tidal waters.

We therefore proposed that the Rivers Board should be empowered, subject to appeal to the Central Authority, to call upon a local authority to adopt some method of purification in cases where purification was necessary.

331. Professor Letts and Dr. Adeney kindly agreed to collect and collate the results of investigations bearing on the question of standards for tidal waters, as regards offensive putrefaction, and injury to fish, and they have presented to us a report on this subject which is contained in Appendix VI.

Their report contains the results of much original work as well as the results, which they have brought together, of the work done by other observers.

Professor Letts and Dr. Adeney have devoted a large amount of time to the work, and we are greatly indebted to them for their report, which is a document of considerable value.

The report affords further proof that any provisions which may be enacted for dealing with the pollution of tidal waters must be of an elastic character.

As an appendix to the report, Dr. Gilbert Fowler has supplied a memorandum as to the results of some observations which he made as to the discharge of septic tank sludge into an estuary near Ipswich.

PART VIII.—SUMMARY OF CONCLUSIONS AND RECOMMENDATIONS.

(I) PREVIOUS REPORTS.

Interim Report. Cd. 685 [1901].

332. Our first Report was of an interim character and contained the following conclusions :—

(1) No land is entirely useless for purification of sewage, "but in the case of stiff clay and peat lands "the power to purify sewage seems to depend on the depth of the top soil."

"There are, of course, numerous gradations in the depths of top soil which are met with in nature, and "it is not easy to draw the line between lands which contain a sufficient depth to justify their use, and lands "which do not."

"We are, however, forced to conclude that peat and stiff clay lands are generally unsuitable for the "purification of sewage, that their use for this purpose is always attended with difficulty, and that where "the depth of top soil is very small, say 6 inches or less, the area of such lands which would be required "for efficient purification would in certain cases be so great as to render land treatment impracticable."

(2) ". . . we are satisfied that it is practicable to produce by artificial processes alone either from sewage, "or from certain mixtures of sewage and trade refuse, such, for example, as are met with at Leeds and Manchester, effluents which will not putrefy, which would be classed as good according to ordinary chemical "standards, and which might be discharged into a stream without fear of creating a nuisance."

"We think, therefore, that there are cases in which the Local Government Board would be justified "in modifying, under proper safeguards, the present rule as regards the application of sewage to land."

(3) ". . . as a result of a large number of examinations of effluents from sewage farms and from artificial "processes we find that while in the case of effluents from land of a kind suitable for the purification of sewage "there are fewer micro-organisms than in the effluents from most artificial processes, yet both classes of "effluents usually contain large numbers of organisms, many of which appear to be of intestinal derivation, "and some of which are of a kind liable, under certain circumstances at least, to give rise to disease."

"We are of opinion, therefore, that such effluents must be regarded as potentially dangerous, and we "are considering whether means are available and practicable for eliminating or destroying such organisms, "or, at least, those giving rise to infectious diseases."

(4) "It is of the utmost importance that the simplest possible means should be provided for adequately "protecting all our rivers," . . . and "it will be desirable, probably for some time to come, that scientific "experiments should be carried on in order to ascertain all the real dangers of pollution, against which they "should be protected."

"In the present state of knowledge, and especially of bacteriology, it is difficult to estimate these dangers "with any accuracy, and it seems quite possible that they should be either exaggerated or under-valued "according to the pre-disposition of those who have to deal with them. An authority, guided by medical "considerations, might not unnaturally be inclined to insist on a degree of purity which may ultimately "prove in certain cases to be uncalled for, while another authority, with its mind fixed upon economy, "might shrink from taking essential precautions."

. . . "the general protection of our rivers is a matter of such grave concern as to demand the "creation of a separate Commission, or a new department of the Local Government Board, which shall be "a Supreme Rivers Authority, dealing with matters relating to rivers and their purification, and which, "when appeal is made to them, shall have power to take action in cases where the local authorities have "failed to do so."

Second Report. Cd. 1178 [1902].

333. Our second Report was a formal document covering certain scientific papers which were presented as an appendix to that Report.

Third Report. Cd. 1486 [1903].

334. In our third Report we dealt with the relations between local authorities and manufacturers in regard to the disposal of manufacturing effluents. We found that the present state of the law was most unsatisfactory, that the attitude of local authorities towards manufacturers had differed widely, and that many manufacturers were seriously handicapped. Our investigations showed that purification of trade effluents by the local authority is in the great majority of cases practicable ; purification by the manufacturer is in some cases difficult, if not impracticable ; while purification by the manufacturer would generally be more costly than purification by the local authority.

It also appeared that the local authorities, as well as the manufacturers, were of opinion that there should be laid on the local authority a distinct obligation to receive trade effluents.

335. Our recommendations on this point were as follows :—

"We are, therefore, of opinion that the law should be altered so as to make it the duty of the local "authority to provide such sewers as are necessary to carry trade effluents as well as domestic sewage, and "that the manufacturer should be given the right, subject to the observance of certain safeguards, to dis- "charge trade effluents into the sewers of the local authority if he wishes to do so."

"We do not think it possible to provide, by direct enactment, what these safeguards should be. In "each district it would probably be desirable that the local authority should frame regulations which should "be subject to confirmation by a Central Auuthority. In most cases however, these regulations could provide "definite standards for the different manufacturers as regards preliminary treatment, and it appears from "the evidence that manufacturers would much prefer to have standards to work to."

"Power to vary the standards or to dispense with them altogether in special cases would be necessary."

"Although the duty of receiving trade effluents should, we think, be imposed on the local authority, "cases may arise in which they should be wholly or partially relieved of it."

"For example, we find that in some instances the effluent discharged from the manufactory is of a com- "posite character, the greater part of which might with advantage be easily dealt with by the manufacturer "if it were kept separate. In such cases we think the manufacturer would generally be willing to adopt "this course, but provision is necessary for those cases in which the local authority and manufacturer could "not agree."

"Further, although we have received no conclusive evidence to show that there are trade effluents which "could not be purified by the local authority, we do not deny the possibility of such cases arising."

"And it is possible that in some cases, as, for example, of a large manufactory being newly established in "a small district, it might be necessary to relieve the authority of the obligation to treat the trade effluent "or to enable them to exact some special contribution from the manufacturer, not only for the cost of treat- "ment, but also towards capital expenditure."

"It is obvious, therefore, that some tribunal will be required for settling differences between the local "authority and the manufacturer, and for relieving the local authority in exceptional cases, either wholly "or partially, of their obligation to provide sewers and disposal works of sufficient capacity for trade effluents "as well as ordinary sewage."

"We are of opinion that generally no special charge should be made on the manufacturer in those cases "in which the regulations as to preliminary treatment are complied with."

"As we have already stated, it is desirable that, wherever practicable, some preliminary treatment "should be carried out by the manufacturer."

"But where the manufacturer is unable to comply with these regulations we consider that the local "authority should be empowered to make a special charge."

"Power should also be granted to make a special charge, even when preliminary treatment is adopted, "where there are exceptional circumstances as regards volume, quality or otherwise."

Settlement of Differences Between Local Authorities and Manufacturers.

336. The chief questions upon which we considered that differences might arise were :—

(1) The refusal of a local authority to allow a particular trade effluent to enter their sewers.

(2) The refusal of a local authority to construct or enlarge sewers for the purpose of a particular manufactory.

(3) The question of varying general regulations as to preliminary treatment by the manufacturer.

(4) The amount of the special charge to be imposed on the manufacturer.

(5) The removal of sludge.

The balance of opinion we found to be strongly in favour of the view that for the settlement of these questions it is necessary to constitute a Central Board possessing adequate technical knowledge, such as the Supreme Rivers Authority which we recommended in our Interim Report.

As regards this matter we reported as follows :—

"We have been struck by the large sums which have been expended in appeals to Courts, but apart "from the question of expense we are strongly of opinion that the ordinary Courts are not suitable for the "determination of these questions, and we venture to think that the judgment of the Master of the Rolls "in the case of Attorney-General *v.* Whitmore, to which we have already referred, clearly supports this view. "His comment that 'the evidence was very complicated, the expert witnesses who were called not only giving "evidence quite inconsistent with one another, but some of them giving evidence in cross-examination which "was quite inconsistent with what they said in examination in chief,' might apply to many similar cases."

"The scientific questions to be solved would in most instances be capable of actual determination by "a properly-equipped Central Authority, and there can be little doubt that such direct proof would be far "less costly than the process of endeavouring to arrive at the truth through the evidence of expert witnesses "in a Court of Law."

"Moreover, the matters to be determined include, not only scientific questions on which witnesses may "be expected to differ, but also considerations of an administrative character which should more properly "be dealt with by a Government Department."

"Further, we find that a Central Authority possessing adequate technical knowledge, would command "the confidence of local authorities and manufacturers."

"In our opinion a properly equipped central authority is essential, and we unhesitatingly recommend "the creation of such an authority."

"In the interests of river purification as well as of the trade of the country we consider it is of the highest "importance that the changes in the law which we have recommended should be made. But these changes "would not in our opinion, be of much use apart from the creation of a Central Authority for the determination "of differences between the local authority and the manufacturer."

"If the settlement of these differences be left to the ordinary Courts, differential treatment of manu- "facturers, with all the objections to it, will be certain to continue."

We also recommended that, for the due protection of rivers, River Boards should be formed for other parts of the country, similar to the three which already exist in Lancashire and Yorkshire, and that these boards should be empowered to determine, subject to appeal to the Central Authority, certain of the differences between local authorities and manufacturers.

We further advised that it should be the duty of Rivers Boards to inspect public water supplies and to report to the Central Authority any cases of dangerous pollution of such supplies which they may detect; and that the Central Authority should be empowered, after due inquiry, to order the purveyors of the water to adopt such means as, in the opinion of the Central Authority, were reasonable and necessary for removing or diminishing the danger.

We also recommended that the Central Authority might, with the aid of the Rivers Boards, very properly collect such information as is available throughout the country in regard to waste of water by pumping from mines, and in regard to the abstraction of water from one district, for the supply of another district, to the detriment of the water supply of the district from which the water was taken. We consider that the collection of such information should precede the consideration of the question whether legislative interference in regard to these matters is desirable.

Fourth Report. Cd. 1883 [1904].

337. In our fourth Report, we dealt with the pollution of tidal waters, with special reference to the contamination of shell-fish. We stated that:—

"After carefully considering the whole of the evidence on this point, we are satisfied that a considerable "number of cases of enteric fever and other illness are caused by the consumption of shell-fish which have "been exposed to sewage contamination; but in the present state of knowledge, we do not think it possible "to make an accurate numerical statement, at any rate as regards the whole country."

"There can, however, be no doubt that the evil is sufficiently grave to demand a remedy."

Our main recommendation for dealing with the evil was stated in the following terms:—

"After carefully considering the whole of the evidence, together with the results of our own investiga- "tions and local inquiries, we are strongly of opinion that the only way in which this evil can be effectively "dealt with is by placing tidal waters under the jurisdiction of a competent authority, and conferring on "that authority power to prevent the taking of shell-fish for human consumption from any position in which "they are liable to risk of dangerous contamination, and to enforce restrictions as regards pollution, and "as regards waters, foreshores, pits, ponds, beds and layings in which shell-fish are fattened or stored, as and "when required."

"For this purpose the powers of the authority must be elastic. The case of each river and estuary is a "problem by itself, and it would not be practicable to fix by enactment any standard or standards which would "be generally suitable to the widely different conditions of different cases. Moreover, as the conditions are "shifting in character, it is necessary to provide some permanent machinery by which restrictions can be "varied."

After considering various alternative suggestions as to the Controlling Authority, we stated that:—

"We entirely agree with the view which has been pressed upon us by a large number of witnesses that "Rivers Boards would be the most suitable bodies in whom to vest the local control which we are now dis- "cussing. Their control over inland waters is of a similar character to the control which is required over "tidal waters (estuarial and other), and it is desirable and fitting that their jurisdiction should be extended "to tidal waters for public health purposes. There are indeed no other local bodies possessing the "necessary qualifications, and the only practicable alternative to giving them jurisdiction would seem to "be to place the whole control in the hands of a Central Department."

We recommended therefore :—

"That the necessary power of control over the pollution of tidal waters, and over waters, foreshores, "pits, ponds, beds, and layings where shell-fish are grown, fattened or stored, should be vested in the Rivers "Boards, subject to appeal to a central authority."

In the Report we set forth, in detail, the procedure which the Rivers Boards and Central Authority should follow. We also dealt with the question of the means which should be adopted for avoiding danger from the consumption of foreign shell-fish.

As regards other evils, besides the contamination of shell-fish, which had to be guarded against in the case of discharge of sewage into tidal waters, we made recommendations dealing with these matters.

SUMMARY OF CONCLUSIONS AND RECOMMENDATIONS.

(2) PRESENT REPORT.

General Conclusion.

338. It is practicable to purify the sewage of towns to any degree required, either by land treatment or by artificial filters, and there is no essential difference between the two processes. Page 9.

The main questions, therefore, to be considered in the case of a town proposing to adopt a system of sewage purification are, first, what degree of purification is required in the circumstances of that town, and of the river or stream into which its liquid refuse is to be discharged; and, secondly, how the degree of purification required can, in the particular case, be most economically obtained.

Removal of Suspended Matters.

We find that it is generally desirable to remove from the sewage, by a preliminary process, a considerable proportion of the grit and suspended matters, before attempting to purify the sewage on land or filters. Page 18.

Sedimentation Tanks.

339. *Quiescent Sedimentation.*—Two to three hours quiescence is usually sufficient to produce a tank liquor fairly free from suspended solids, but owing to the fact that some sewages contain a larger proportion than others of solids that settle very slowly, no general rule can be laid down as to the necessary period of quiescence. With this form of treatment the deposit in the tanks should be frequently removed. Page 19.

Continuous Flow Sedimentation.—The amount of settlement effected does not depend alone upon the period of flow, but upon a number of other factors. If the tank liquor is to be treated upon filters of fine material, the period of flow should generally be from 10 to 15 hours. The tanks should be cleaned out at least once a week. Page 20

Septic Tanks.

340. All the organic solids present in sewage are not digested by septic tanks, the actual amount of digestion varying with the character of the sewage, the size of the tanks relative to the volume treated, and the frequency of cleansing. With a domestic sewage, and tanks worked at a 24-hours rate, the digestion is about 25 per cent. Page 21.

The liquor issuing from septic tanks is bacteriologically almost as impure as the sewage entering the tanks. Page 22.

Domestic sewage which has been passed through a septic tank is not more easily oxidised in its passage through filters than domestic sewage which has been subjected to chemical precipitation or simple sedimentation. Page 22.

Page 25. No definite rules can be laid down as to how long a septic tank should be run without cleaning. In the case of small sewage works (serving populations of say 100 to 10,000 persons), the tanks should generally be allowed to run, without cleaning, so long as the suspended matter in the tank liquor shows no signs of affecting the filters injuriously. For larger works it would generally be advisable to run off small quantities of sludge at short intervals of time.

Page 26. The rate of flow through a septic tank is a matter in which the needs of each place require special consideration, but at few places should the sewage be allowed to take longer than 24 or less than 12 hours to flow through the tank. In no case should less than two tanks be provided, and they should be arranged so that, if necessary, one tank can be used alone.

Page 28. As regards digestion of sludge and quality of tank liquor, a closed tank possesses no advantages over an open tank. There is less risk of nuisance if the tank and the feed channels to the filters are covered in.

Page 29. By passing septic tank liquor through tanks of a size sufficient to hold about one quarter of the day's flow, with the addition of from 2 to 3 grains of lime per gallon to the liquor, the suspended solids in the liquor are materially reduced, a considerably larger quantity of the liquor can be treated per cube yard of filter, and the offensive character of the liquor is largely destroyed.

Chemical Precipitation.

Page 30. 341. In the case of sewages which contain certain trade waste, and strong sewages from water-closet towns, it is generally desirable to subject the sewage to some form of chemical treatment before attempting to oxidise the organic matter contained in it. In most cases careful chemical precipitation materially aids the deposition of the suspended solids, and facilitates subsequent filtration.

Page 30. No general rule can be stated with regard to the capacity of precipitation tanks. With continuous flow, an eight hours rate is usually sufficient to produce a fairly good tank liquor from a domestic sewage of average strength.

Page 30. If sewage is allowed to remain quiescent in the tank, two hours settlement would usually suffice.

Relative Cost of Different Tank Treatments.

Page 43. 342. In the absence of special circumstances favouring a particular plan, it would appear that there is very little difference in annual cost between the various methods of tank treatment when taken in conjunction with the cost of subsequent filtration through percolating filters, assuming that the kind of filter adopted in each case is that which is best adapted to the particular tank treatment provided.

Filters.

Page 52. 343. Within ordinary limits, the depth of a contact bed makes, practically, no difference to its efficiency per cube yard.

Page 53. We think that it would be generally inadvisable to construct contact beds of a greater depth than 6 feet or of a less depth than 2 feet 6 inches.

Page 87. For practical purposes and assuming good distribution, the same purification will be obtained from a given quantity of *coarse* material, whether it is arranged in the form of a deep or of a shallow percolating filter, if the volume of sewage liquor treated per cube yard be the same in each case.

Page 87. With regard to percolating filters of *fine* material, if the liquid to be purified were absolutely free from suspended and colloidal solids, and if thorough aeration could be maintained, the statement just made for filters of coarse material might possibly hold good for filters of fine material also. In practice, however, these conditions can scarcely be maintained with large rates of flow, and we think that the greatest efficiency can be got out of a given quantity of *fine* material by arranging it in the form of a shallow filter rather than of a deep filter. But we are not in a position to make an exact quantitative statement as to the difference in efficiency of the two forms.

344. The amount of sewage which can be purified per cube yard of contact bed or of percolating filter varies—within practical limits—nearly inversely as the strength of the liquor treated. This statement is based on the assumption that the size of the material of which the filter is composed is, in each case, suitable to the character of the liquor treated, and that the material is arranged at the proper depth to secure maximum efficiency. Page 119.

Detailed particulars as to the amounts which can be treated per cube yard of filter are given on page 117.

Taking into account the gradual loss of capacity of contact beds, a cubic yard of material arranged in the form of a percolating filter will generally treat about twice as much tank liquor as a cubic yard of material in a contact bed. Page 119

In the case of sewage containing substances which have an inhibitory effect upon the activity of micro-organisms, the working power per cube yard of filter of either type may be more nearly equal. This point, however, is not clearly established. Page 119.

Percolating filters are better adapted to variations of flow than contact beds. Page 119.

Effluents from percolating filters are usually much better aerated than effluents from contact beds, and, apart from suspended solids, are of a more uniform character. On emptying a contact bed, the first flush is usually much more impure than the average effluent from the bed. Page 119.

The risk of nuisance from smell is greater with percolating filters than with contact beds. Page 119.

With percolating filters there is apt to be nuisance from flies, especially with filters constructed of coarse filtering material. In the warmer months of the year, such filters swarm with members of the *Psychodidae*, which, though appearing to breed and develop in the filters, may usually be seen in large numbers on the walls of houses, or buildings close to or on the works. Page 119

Treatment of Sewage on Land.

345. There is no essential distinction between effluents from land and effluents from artificially constructed filters. Pages 137 and 142.

Effluents from those soils which are particularly well adapted for the purification of sewage contain only a very small quantity of unoxidised organic matter, and are usually of a higher class than effluents from artificial filters as at present constructed and used. Page 142.

Effluents from soils which are not well adapted for the purification of sewage may often be very impure. Page 142.

Sludging of Mill Dams.

346. In any case in which the Rivers Board should be of opinion that the sludging of a mill dam by turning the accumulated sludge into the stream would give rise to a nuisance, and that it would be financially practicable for the mill owner to adopt some other method of cleansing the dam, the Rivers Board should be empowered, by notice, to direct the mill owner not to turn the sludge into the stream. Page 191.

It should be provided that any mill owner deeming himself aggrieved by such a direction, might, within some fixed period, appeal to the Central Authority. The decision of the Central Authority should be final.

Should any cases arise, in which it is important that the sludge should not be turned into the stream, but in which the Rivers Board are of opinion that the cost of adopting any other method of cleansing the dam would be prohibitive to the millowner, we recommend that the Rivers Board should be empowered to represent the case to the Central Authority, and that the Central Authority should be empowered. after due enquiry, to direct that the sludge shall not be turned into the stream. If the Central

Authority should be satisfied that the cost of adopting some other method of cleansing the dam would be greater than the millowner could be reasonably called upon to bear, they should be empowered to direct that a portion of the cost should be borne by the local authorities whose districts would be benefited.

Effect of Trade Effluents on Sewage Purification.

Page 192. 347. All the trade effluents of which we have had experience interfere with or retard processes of purification to some extent, but we are not aware of any case where the admixture of trade refuse makes it impracticable to purify the sewage upon land or by means of artificial processes, although in certain extreme cases special processes of preliminary treatment may be necessary.

Nuisance from Smell.

Page 195. 348. All sewage works are liable, at times, to give off unpleasant smells ; they should, therefore, be situated away from dwelling houses, wherever this is practicable.

The nuisance is apt to be considerably greater where the sewage contains brewery refuse in any quantity ; but, on the other hand, the presence of some trade effluents, such, *e.g.*, as iron salts or tarry matters, tends to render the process of purification less offensive.

The extent of the risk of nuisance depends, however, not only on the character of the sewage, but also on the method of treatment adopted.

General Observations bearing on Choice of a Method of Sewage Treatment.

Page 202. 349. The selection of a method of sewage disposal should depend primarily on local conditions.

If a sufficient quantity of good land, to which the sewage can gravitate, can be purchased for about £100 an acre, land treatment would usually be the cheapest method to adopt.

In cases where only clay land is available, it would generally be cheaper and more satisfactory to provide artificial filters.

Page 202. 350. Given conditions favourable to each process, there is little difference as regards cost between any of the different forms of tank treatment when these are considered along with the cost of subsequent filtration.

Page 202. Single contact will, generally, only yield a good effluent where the sewage to be treated is weak, and then only after good preliminary treatment. For the purification of partially settled weak sewage, and for well, as also for partially, settled sewage of average strength, if the case is one in which a good effluent is required, double contact is necessary, while if a strong sewage has to be treated, triple contact is necessary, unless the preliminary treatment is exceptionally good.

Page 203. In nearly every case a greater rate of filtration per cube yard can be adopted if the material is arranged in the form of a percolating filter, than if it is used in contact beds. In many cases the rate of filtration through percolating filters may be double or nearly double what it could be with contact beds.

Pages 67 & 203. Where the liquor to be treated contains much suspended matter, it is usually advisable to construct filters, whether contact or percolating, with coarse filtering material. Where the preliminary treatment has effectively removed the greater part of the suspended matter, it is best to use fine material in the filters.

Storm Overflows on Branch Sewers.

Page 209. 351. Storm overflows on branch sewers should be used sparingly, and should usually be set so as not to come into operation until the flow in the branch sewer is several times the maximum normal dry weather flow in the sewer. No general rule can be laid down as to the increase in flow which should occur in the branch sewers before sewage is allowed

to pass away by the overflow untreated. The Rivers Board, or in districts where there is no Rivers Board, the County Council, should have power to require the local authority to alter any storm-overflows which, in their opinion, permit of an excessive amount of unpurified sewage to flow over them. The local authority should have the right to appeal to the Central Authority in any case in which they consider that the requirement of the Rivers Board is unreasonable or impracticable of fulfilment.

The general principle should be to prevent such an amount of unpurified sewage from passing over the overflow as would cause nuisance.

Treatment of Storm Water Sewage at the Works.

352. As a general rule, special stand-by tanks (two or more) should be provided at the works, and kept empty for the purpose of receiving the excess of storm water which cannot properly be passed through the ordinary tanks. As regards the amount which may be properly passed through the ordinary tanks, our experience shows that in storm times the rate of flow through these tanks may usually be increased to about three times the normal dry weather rate without serious disadvantage. Page 210.

The overflow at the works should be made from these special tanks, and should be arranged so that it will not come into operation until the tanks are full.

Special filters which are only used in times of storm are not usually efficient, and should not be provided.

Any extra quantity of sewage arriving at the works in storms, which has to be filtered, should be treated on the ordinary filters, which should be made sufficiently large for the purpose.

As regards the size of the stand-by tanks, the amount of storm water sewage to be filtered, and the arrangements generally for dealing with the storm sewage at the outfall works, the Rivers Board or the County Council in areas in which no Rivers Boards have been established, should have similar power to that which we have proposed in regard to overflows on branch sewers, and the local authority should have a similar right of appeal to the Central Authority.

In most cases it will probably suffice to provide stand-by tanks capable of holding one quarter of the daily dry weather flow, and it will not be necessary to provide for *filtering* more than three times the normal dry weather flow.

Under the arrangements which we recommend no storm sewage arriving at the outfall works would be discharged without some settlement.

Separate Systems of Sewers.

353. In any case in which a local authority wishes to adopt the separate system of drainage for the whole or any part of their district, they should apply to the Central Authority, and that Authority should be empowered to confer on the local authority, by order, such powers as are required. Page 216.

As regards the powers that are required, the provisions which are generally contained in local Acts in respect of this matter seem to be defective. If separate sewers are provided, the local authority should have a clear power to enforce the provision of separate drains, but the local Acts to which our attention has been drawn do not modify the powers of the local authority under the general law in regard to bye-laws as to the drainage of houses. Moreover, the powers of the local authority should not necessarily be limited to new streets and new houses.

As a general rule, the expense of altering existing drains should fall on the local authority, and there may be some instances in which it would be equitable that they should bear some portion of the additional cost even in the case of new roads.

The Central Authority should, therefore, have power to include in their Order such provisions for the allocation of the cost as they consider equitable, having regard to the local circumstances.

Standards for Sewage Effluents.

Page 218. 354. Our terms of reference require us to have regard to the "*economical* and efficient" discharge of the duties of local authorities, and in view of the importance of not requiring a local authority to incur any further expenditure on sewage disposal than the circumstances of its area require, we feel strongly that the law should be altered so as to allow local circumstances to be taken into account.

Page 220. We recommend that the Central Authority should determine the nature of the tests which are to be applied for the purpose of standards, and that it should be made the duty of the Rivers Board, or of the County Council in areas not under the jurisdiction of a Rivers Board, to determine, from time to time, subject to appeal to the Central Authority, what standards should be adopted.

In the first instance it would be convenient that the Central Authority should prescribe one standard for all non-tidal waters, in place of the existing statutory provisions. It would then rest with the Rivers Board or County Council to fix, subject to appeal to the Central Authority, a higher or lower standard in any case in which they were of opinion that the circumstances required or justified a different standard.

We further recommend that no action should be allowed to be brought in respect of damage alleged to be due to the discharge of an effluent which complies with the standard fixed for the water into which it is discharged, but that in such cases complaint should be made to the Central Authority, and, if a *prima facie* case is made out, that Authority should ascertain whether the complaint is well founded, and should be empowered to fix a different standard if the circumstances are shown to require it.

In cases where it is alleged that the effluent does not comply with the statutory standard, and that damage is caused by the discharge of such effluent, action should be brought in the ordinary Courts.

But any questions arising as to whether the effluent complies with the statutory standard, or as to whether the damage has been caused by the discharge of the effluent in respect of which complaint is made, should be referred by the Court to the Central Authority for determination. The costs of such determination should be borne by the parties to the action in such proportions as the Court may determine.

Power should be conferred on the Central Authority to suspend, from time to time, the operation of any standard, to allow time for the construction of works, or for any other reason which, in their opinion, justified such suspension.

Tests for Sewage Effluents in Relation to Standards.

Page 222. 355. According to our present knowledge, an effluent can best be judged by ascertaining, first, the amount of suspended solids which it contains, and, second, the rate at which the effluent, after the removal of the suspended solids, takes up oxygen from water.

In applying this test it is important that the suspended solids should be removed, and estimated separately.

For the guidance of local authorities we may provisionally state that an effluent would generally be satisfactory if it complied with the following conditions:—

(1) That it should not contain more than 3 parts per 100,000 of suspended matter; and

(2) That, after being filtered through filter paper, it should not absorb more than:

(*a*) 0·5 part by weight per 100,000 of dissolved or atmospheric oxygen in 24 hours.

(*b*) 1·0 part by weight per 100,000 of dissolved or atmospheric oxygen in 48 hours; or

(*c*) 1·5 parts by weight per 100,000 of dissolved or atmospheric oxygen in 5 days.

The Central Authority.

356. To secure the economical and efficient discharge of the duties of local authorities, and others, in regard to pollution, and adequately to protect the public health and the amenities of rivers, the statutory provisions in regard to these matters must be of an elastic character.

The conditions of different cases vary to such an extent that the necessary control cannot, in our opinion, be provided by any direct enactment which could be enforced by the ordinary Courts.

Throughout our Reports, this fact has been fully recognised, and we have proposed, in regard to many matters, that ultimate control should be vested in an adequately equipped Central Administrative Authority, and that, as far as practicable, the local Rivers Board should, in accordance with regulations framed by the Central Department, act as a first tribunal.

Among the more important questions which have to be dealt with under the new conditions of administration which we are contemplating, are the following :—

(i.) Disputes between local authorities and manufacturers as to the terms and conditions on which trade effluents shall be admitted into sewers ;

(ii.) The control of shell-fish layings so as to prevent the taking of shell-fish for human consumption from positions in which they are liable to risk of dangerous contamination.

(iii.) The protection of water supplies from pollution.

(iv.) The collection of information as to the water supplies available in various parts of the country.

(v.) The collection of information as to the need of water in various parts of the country.

(vi.) The settlement of standards for different reaches of water.

(vii.) Conferring powers on local authorities, in suitable cases, to provide separate systems of sewers for surface water and to enforce the provision of separate drains.

(viii.) The settlement of questions as to the extra amount of sewage which a local authority should be required to treat during storms.

There are also numerous questions in regard to the purification of polluting liquids which, in the interests of the public, have still to be worked out, and it is essential that the Central Authority should be properly equipped for undertaking such special investigations as they may from time to time find necessary, and for collecting and collating the work done by others.

Since the date of our appointment considerable developments have taken place in regard to the disposal of sewage, and there is every reason to think that further changes will occur in the future.

Unless the Central Department keep in close touch with all such changes, and from time to time report on them, it is not possible for local authorities throughout the country fully to utilise the results of valuable work which is being done at many places, and hence, to perform their duties in the most economical as well as efficient manner.

The Position of our Inquiry.

357. In this Report we have dealt with the main question of what methods of sewage disposal may properly be adopted by local authorities. The remainder of our work will be chiefly concerned with the disposal of trade effluents when not mixed with sewage.

We have already investigated the disposal of distillery effluents, and shall issue a separate Report on this subject very shortly.

Concurrently with our investigation of the methods available for disposing of other trade effluents we shall continue our observations on the effect of discharging effluents of known composition into streams, with a view to reporting more fully on the question of standards and tests.

Page 188. We are continuing, for another season, the experiments on the manurial value of sewage sludge, and are also making some observations on a few other points.

MINUTES OF EVIDENCE

TAKEN BEFORE THE

ROYAL COMMISSION

APPOINTED TO

Inquire and Report: First, what method or methods of treating and disposing of Sewage (including any Liquid from any Factory, or Manufacturing Process) may properly be adopted consistently with due regard for the requirements of the existing Law, for the protection of Public Health, and for the economical and efficient discharge of the duties of Local Authorities; and if more than one method may be so adopted, by what rules, in relation to the nature or volume of Sewage, or the Population to be served, or other varying circumstances or requirements, should the particular Method of Treatment and Disposal to be adopted, be determined; and, secondly, to make any Recommendations which may be deemed desirable with reference to the Treatment and Disposal of Sewage.

SIXTY-EIGHTH DAY.

Tuesday, 16*th February*, 1904.

PRESENT:

Colonel T. W. HARDING, J.P. (*in the Chair*).

Sir MICHAEL FOSTER, K.C.B., F.R.S., M.P.
Sir WILLIAM RAMSAY, K.C.B., F.R.S.
Mr. W. H. POWER, C.B., F.R.S.
Major-General CONSTANTINE PHIPPS CAREY, C.B., R.E.

Mr. F. J. WILLIS, *Secretary*.

DR. COWIE, called; and Examined.

19728. (*Chairman.*) Dr. Cowie, we had the pleasure of seeing you when we were in Scotland. Would you be good enough, therefore, to act as introducer of the gentlemen about you? I understand we have before us the Provost of Rothes?—(*Dr. Cowie.*) No, he is not here, sir.

19729. Then would you tell us who these gentlemen are?—(*Dr. Cowie.*) Mr. Allan, Mr. Thorne, Mr. Hopkins, Mr. James Robertson, Mr. Doig, Mr. Grant Glen Grant, Mr. Fergusson (Jura), Mr. Brown (Campbeltown), Mr. Mustard.

19730. Are all these gentlemen interested in distilleries?—Every one of them.

19731. And is this deputation representative of some association—if so, what?—It represents the whole Scotch malt distilling trade.

19732. What is the name of the association?—Well, we will take it this way: There are here representatives from the South, East, and West of Scotland Malt Distillers' Association, as well as from the North of Scotland Malt Distillers' Association, to which I belong.

19733. Then this is a combination of associations?—That is so.

19734. And I understand that you come before us in consequence of the difficulty which lies before distillers owing to decisions which have been given by the Court of Session in actions at the instance of John Ritchie Findlay *v.* Dailuaine-Talisker Distillery Co., Limited, and Dailuaine-Talisker Distillery Co. *v.* James W. H. Grant, the particulars of which you have put before us?—That is so.

19735. I understand that Dr. Cowie, on behalf of the deputation to-day, has a statement to make to the Commission?—That is so.

19736. Will Dr. Cowie be good enough to proceed?—Colonel Harding and gentlemen, the deputation that I have the honour to introduce to you to-day represents practically all the distillery interests in Scotland. During the year 1902 the output from these distilleries was over 29,000,000 gallons, representing about £15,000,000 sterling in Imperial revenue per annum. There are 167 such works in Scotland. My interest, as you know, is more particularly connected with the North of Scotland, and you will see from the map which has been put in that a great number of these works are concentrated round the Spey Valley. The gentlemen who are here to-day, however, represent Islay and Campbelltown, the south, the west, and the east—practically all the malt distillers of Scotland. Although the question has been more acute in our district, it is being raised all over the country. The industry which we represent, as you are aware, employs a large number of workmen, both directly and indirectly. It affords an outlet for barley and other agricultural products of the neighbourhoods where the distilleries are situated, and also gives cheap cattle food, without which, during the last two years, I may say, in our part of the country, the farmers in some of our Highland glens would have been reduced to dire extremity. As it is, we know they have had very bad crops for two years, no root crop, and their white crop has failed, and they have had to depend for food for their cattle on what they have got from the distilleries. Farmers have been coming to my place, five, six, or seven miles, to drive away food for their cattle. I am not able to give you figures regarding the amount of capital invested in this industry, but it is enormous. For some years past the question of the disposal of waste products from the distilleries has been a burning one between the distiller and riparian proprietors. Into the composition of these by-products it is unnecessary for me to enter, as the Commission has already investigated this on their own account. But it is necessary for me to touch upon the difficulty and the gravity of the problem. I may remind you that during your visit to the north last May, we were able to show you varied and extensive works for the purification of these bye-products, and I think we were able to convince you at that time that we were making earnest and every possible endeavour conscientiously to grapple with this problem. I think you were also told that the distillers on the Spey offered to construct a pipe to the sea at a cost of from £40,000 to £50,000, but that

6225—Ap. I. 1250.—Wt. 9302. 9/08. Wy. & S. 3562*r*.

Dr. Cowie.

16 Feb. 1904.

the proprietor of the fishings at the mouth of the river, the Duke of Richmond and Gordon, objected to this proposal. We also, as you know, offered a premium for an efficient system for the disposal of our sewage, but nothing came of it. I must say that perhaps at one time the distillers, like other manufacturers, when this problem confronted them, were a little slow to move till they saw how things would go, but I have to impress on the Commission that I am certain every distiller is now anxious to find some way out of this trouble and to meet the complaints that have been made against them by the proprietors. As you have said, sir, it is owing to the judgments of the Court of Session against this distillery company and others that are now pending in the court (because this is not an individual instance, but it is a string of a number of cases that are instituted against distillers), the distillery industry has become thoroughly alarmed, and they quite see that it is only a matter of time when this large and important industry will be absolutely shut up unless something can be done to remedy the trouble. We have come to you to-day to ask you to send your experts to investigate and see what can be done, with the view to fixing some standard of purity up to which it would be safe for the riparian proprietors to receive effluents from distilleries into the stream; also to investigate the methods which you saw working, such as evaporation, incineration, and destruction works, which are now in danger of being interdicted on account of the smell arising from the burning of the pot-ale, and also to report on what you would consider the best and most efficient means of solving the question. If, unfortunately, as we are led to understand, your staff is fully occupied at the present moment observing works with a view to a further report on sewage effluents, and sewage and trade effluents mixed, so that you cannot at once investigate the methods available for dealing with distillery refuse, we would offer the suggestion that you should ask the principal proprietors on the Spey to come before you and give their views, and see if a *modus vivendi* between the distillers and the proprietors could not be arrived at until such time as you are able to investigate and report upon the standard of purity which would be reasonable to all concerned. I may say that on every occasion upon which we have asked the riparian owners for some indication as to what will satisfy them they have invariably said, "We just want pure water, and we do not care how you arrive at this." That in our opinion is practically impossible—is an absolute impossibility. There is another point which I should like to bring before the attention of the Commission. I think it struck you when you came up last spring that sufficient land was probably not employed in many cases in works for purification. Well, a good many distillers—in fact, all distillers—have what they call feus—that is, a freehold for which they pay a large annual rent. When land was required for purification works, these gentlemen from whom we had the feus either asked an exorbitant annual feu duty or refused the land altogether, although at the same time they are receiving large annual payments for the land occupied by the distillery. This is actually the case now at Rothes, as Mr. Grant and Mr. Robertson will tell you. They threaten us with an action for interdict, and then demand £15 to £30 an acre per annum for land which is not worth as many shillings from an agricultural point of view. We would ask you, therefore, gentlemen, if you could possibly see your way to promote legislation by which on application to the County Council or some other local authority it might be possible for distillers and other manufacturers (for the same thing obtains with regard to some other industries in the north) to obtain land at a reasonable price, so that our industries might not be hampered in that way. As I have said before, perhaps we were a little backward at one time in doing what we could to solve this problem, but for the last few years large sums have been spent, and everybody has been doing his very best to arrive at the solution. We would welcome such a proposal as is made in your third report on sewage disposal for England, that some such central authority should be appointed as you propose, to deal with the matter between the manufacturers and local authorities or proprietors. Such a central authority as you recommend would be a far better tribunal than the ordinary courts. We would pray that you would recommend that this should also be extended to Scotland. At present we, as individuals, are spending large sums without any security that the works that are being erected are the best possible available. This could be obviated if your recommendations were accepted, and it would save a great deal of money both to the country and to individuals at large. The landlords, no doubt, are as anxious as we are that money should not be needlessly wasted on works and on useless litigation. If a central authority were appointed, there is no doubt that this would be sufficient to safeguard the interests of all parties. Before drawing my remarks to a conclusion, I would like to say a few words with regard to the fishing rights of the riparian owners on the Spey, and Mr. Grant, who is an old fisherman on the Spey, and who has large experience, will speak to this later. For the last four years we maintain that the damage to fishing has been infinitesimal, if not *nil*, on the Spey, and this is evidenced by the report of the river watchers of the number of fish on the spawning beds during the last two or three seasons; also, indeed, by reports in the newspapers. Since the opening of the fishing season on the Spey on the 11th February last the fishing has been a record one, both from the point of view of the rod fisherman and the netsman. They have, I think, made absolute records in rod fishing, from what I hear. I wish to impress upon the Commission that we distillers do not want in any way to injure the streams or to encroach on the rights of the riparian owners; we only ask reasonable facilities for carrying on our business, and we are in hopes that an interview between you and the riparian owners will bring into proper perspective our respective positions, and convince them that their interests are not being unduly encroached upon by us, and that there must be a little give and take between us before a settlement can be effected. In what I have said with regard to the Spey—you have been hearing so much about it—I have spoken from my own point of view; the other gentlemen can speak for theirs, but I may say the question is acute all over Scotland, and they will be able to tell you so. Well, there are four points that we wish to urge upon you. First, that you may send your scientific staff up to investigate the methods in operation, and to give an opinion as to what is the best possible means of purification of our effluents and to establish some standard of purity. Second, that you urge upon the Government to promote legislation whereby application to a local authority manufacturers may compulsorily obtain land for purification works at a reasonable figure. Third, that you extend the recommendations in your third report to Scotland, so that the interests of the manufacturers as well as those of the landlords may be safeguarded by the appointment of a central authority. Fourth, we venture to suggest that you ask the Duke of Richmond and Gordon, Mr. Menzies of Arndilly, Mr. Findlay of Aberlour, and Mr. Grant of Elchies, and other proprietors to exchange views with you in order that some arrangement may be arrived at until such time as you can report.

19737. Does any other member of the deputation wish to address the Commission?—(*Mr. Grant.*) I have got very little to say, sir. The only thing I should say after the exhaustive statement that Dr. Cowie has given you—the only point I wish to talk about is entirely from a fisher's point of view. I have fished the Spey for 46 years steadily every year, and in my opinion the effluents that are going into the river do not in any way hinder sport—not in the slightest. I have had experience; my father had the fishing below where this Dailuaine Distillery is for 21 years; I fished it during his lifetime, and I had it for five years myself immediately below where the Dailuaine Distillery effluents were going into the river. I have seen the burnt ale coming into the top pool, and it ran down the side, but in the second pool the water ran to the side, and consequently the whole of that pool the burnt ale was distributed right over it, and I have killed many and many a hundred salmon in that pool when that effluent has been going down.

19738. Do you suggest to us that pot-ale is an excellent thing for improving the condition of the river for fisheries?—I do not say that it is an excellent thing for improving the condition of the river, but it does not hinder sport. That is my own personal experience after 46 years.

19739. (*Sir Michael Foster.*) Not only now does it not injure sport, but it has not done so in past years?—Certainly not.

19740. When your proportion was not so good as it is at present?—Certainly not.

19741. (*Major-General Carey.*) On the other hand, you had not got the distilleries four years ago on the Spey, really?—I had; you see, I am both a distiller and a fisherman.

19742. (*Mr. Power.*) What proportion does the effluent from the distilleries bear to the total water in the river at the point you are mentioning?—Oh, infinitesimal.

19743. Infinitesimal as compared with the water in the river?—Oh, certainly. The Spey is a very rapid river, and carries away everything. The pot-ale would simply go down the side, I fancy; probably a matter of 10ft. or 12ft. would be where the pot-ale would come down into the river, and it would remain there unless the body of the river was striking against some other projection so as to mix it all up. Really the pot ale goes down the side.

19744. (*Sir William Ramsay.*) Does it not froth?—Yes.

19744*. Does not that prevent you seeing your cast?—Certainly not.

19745. (*Sir Michael Foster.*) Are your views shared by all fishermen who are fishing in the district—those who are not distillers, simply fishermen?—The fact of the matter is this—that owing to the exhaustive net fishing, salmon have become very scarce. If you do not allow fish up to breed you cannot get fish. In my young days I have seen hundreds and hundreds of fish spawning, and now you will walk miles and not see a pair of spawning fish on the places where there used to be hundreds. For the last 10 years I have had the shooting of Glen Livet, where the Avon, the Livet, and all these streams which are admirably adapted for spawning fish are. While in my young days hundreds of fish were there, you will go and you will walk for a couple of hours without seeing a pair of spawning fish now, simply because thebrood of the fish are killed out by over-netting, so much so that the Duke of Richmond this year has taken off 7½ miles of nets.

19746. (*Chairman.*) It occurs to me, Mr. Grant, that it is scarcely worth while to press that, is it, because I think you yourself would not deny that pot-ale is in itself an evil in that beautiful stream; only you suggest to us that its volume is relatively so small to that of the stream itself that the damage that it may do is not very serious?—It is not serious.

19747. But I think you would probably agree that damage of a sort there is. You cannot suggest that pot-ale is good for the stream in regard to the fisheries?—It does not prevent fish-taking, and it does not kill fish.

19748. I think we need not press that further, because you suggest to the Commission, which is possibly true, that the reduction in the number of fish may be due to other causes altogether than anything in connection with distilling?—Certainly.

19749. And, on the other hand, Dr. Cowie told us just now that the recent condition of the fisheries has been very good. I think he spoke about a record rod-fishing in the Spey, so that I think it is unnecessary to press that further. Do you wish to say anything to the Commission in regard to your own experience—for instance, as to the best way of dealing with the effluents from distilleries?—After what Dr. Cowie has said I can add nothing.

19750. Well, I will not press you for any further information on the question of the fisheries. Does any other member of the deputation wish to add anything to what has been said by Dr. Cowie?—(*Mr. Fergusson.*) I represent the South, and am the Chairman of the South, West, and East of Scotland Malt Distillers' Association. I have been sent here because we wish, along with the other deputies here, to represent the whole distilling industry of Scotland. I may say that in our Association this matter of bye-products does not affect us. Our distilleries are for the most part situated on the seaboard, and we get access to the sea for our refuse. We have some distilleries in the country, and we do not know the moment that we might require to join with the rest in getting some decision arrived at about the impurity adopted in rivers. I would only back up what Dr. Cowie has said on this—that malt distilling is the principal industry of the north of Scotland, and that it provides wages and employment to a great number of places which otherwise would be in abject poverty. Scotch whiskey is becoming a very important stimulant. It is the most popular at the present moment of all stimulants, and it is supposed to be the most wholesome. As these distillers are making the very best malt whiskey, they think it is rather hard that they should not be allowed to carry on the work without unnecessary obstruction. Dr. Cowie has said that they have no wish to adulterate the rivers; they will do everything science can suggest to make their effluents innocuous; but there seems to be something that will not precipitate and they cannot get quit of, and technically it is an adulteration. Well, I suppose they wish some latitude in that respect. I only wish to say, Mr. Chairman and Commissioners, that in our Association we sympathise very much with the difficulty of our brethren in the north, and we would be very glad if some scientific basis could be arrived at which would prevent unnecessary litigation.

19751. Mr. Fergusson, I gather from your observations that the distilleries in Scotland are centred mainly in three districts—on the Forth, the Clyde, and the Spey?—On the Clyde—that is Campbelltown, of course.

19752. And in regard to the Forth and the Clyde—those being large sea arms or tidal streams, the difficulty is not acute there, and therefore the Commission may for the present concentrate their attention upon the acute difficulties on the Spey?—That is so.

19753. There is on that stream quite a large concentration of distilleries?—Yes.

19754. I see on the map a great number of red spots in that district?—Quite so.

19755. And there is also a very beautiful stream which has great fishing value?—Yes.

19756. And therefore really that is an acute spot which we must direct attention to?—That is so.

19757. Now, Dr. Cowie, you have referred to the work which has already been done which some of the Commissioners had the advantage of seeing when they visited Scotland last year. We should be interested in knowing to what extent progress has been made since then. I gather, in the first instance, distillers, like most other manufacturers, were by no means keen to purify their trade effluents; they possibly allowed the matter to drift on too long until the condition became extremely acute. That may be to some extent the cause of their present difficulty, but we did see when we were there several honest attempts at dealing with this difficulty, and those were mainly in three directions. One was in the direction of purification by means of successive passages over contact beds—as many, if I remember right, as eight in one case?—(*Dr. Cowie.*) Yes.

19758. Another direction was the evaporation of the pot-ale which was kept separate from other effluents, which may be less difficult to deal with?—Yes.

19759. And finally, in one case we saw the mixture of the distillery effluent with the domestic sewage, which was attempted to be dealt with by the municipality at Rothes. Well, I cannot say that we were struck with the great success in any of these cases, with the results obtained, except in connection with evaporation where clearly the success was complete, inasmuch as the effluent disappeared altogether, and in one particular case—I think it was the case of the Glendullan Distillery—we found there also that the effluent disappeared altogether, because after being dealt with upon contact beds the filtrate from the beds was pumped to a plateau on the top of a hill, and there distributed over a large area of land, so that none has reached the stream at all?—That was at Coleburn Distillery.

19760. Was that Coleburn Distillery; I dare say you are right there?—At Glendullan they evaporate simply.

19761. That was so; it was at the Coleburn Distillery that they pumped to the top of a hill; and, therefore, there was no effluent; and, therefore, the result was absolute perfection. You cannot get beyond that. In the cases where you had evaporation there also the effluent disappeared; but the whole difficulty then arose in connection with the residual matters, either syrup in the case where there was only partial evaporation, or a manurial ash which was produced where there was complete burning?—Yes.

19762. Now you have spoken to us about the objection which has arisen in connection with the burning; an objection in connection with bad smells arising from the burning?—Yes.

Dr. Cowie.
16 Feb. 1904.

19763. Now are you able briefly to inform the Commission what progress, if any, has been made in these three directions since the Commission visited Scotland last year? For instance, in your own distillery we saw a very complete arrangement of contact beds—I think seven at one time?—Seven.

19764. You were proposing to put an eighth?—Yes.

19765. And you obtained results which were a very obvious improvement on the original effluent that went to the beds, but a result which I think you also thought was scarcely good enough to be turned into the stream. You were proposing then to make some further experiments; possibly you may have something to say to us in regard to them. These matters would guide the Commission somewhat in the decision they will have to come to?—In the autumn I went to see some purification works with Mr. Frye and Mr. Willis, and as the result I put up a continuous filter, which has materially improved the effluent.

19766. At your own works?—At my own works, yes.

19767. With what previous treatment?—First passing it through a sludging compartment, then over a bed consisting of limestone, after this ponding it in seven contact beds, and passing it over a Whitaker Tower. This is our present treatment, and it is giving excellent results. We tried continuous filtration in the contact beds, with tipping spouts, but it did not answer in my case. We had great difficulty with the distributor on the continuous filter; it silted up, and did not work. The local plumber has invented a very efficient distributor; it consists of a circular copper plate, which is perforated; on this plate are soldered, radiating from the centre, perpendicular strips of copper; on this two jets of effluent are made to impinge, which results in a uniform spray being distributed over the filter by the rotation of the plate. The plate is about 4ft. above the surface of the bed. I think this distributor would be useful for sewage as well as for distillery effluent. We have found that the trouble in our contact beds has arisen from yeast cells propagating when the lactic acid in the pot-ale has become considerably neutralised; this takes place in from two to three contacts, and, as a rule, in the fifth or sixth contact we have a neutral effluent. I may tell the Commission that experiments are at present being carried out in the cultivation of yeast in treated pot-ale on these lines, and, I believe, with considerable success, but they are not sufficiently advanced for me to say anything about them.

19768. (*Sir Michael Foster.*) Do you mean with the view to propagate yeast?—To propagate yeast.

19769. Simply for the propagation of the yeast or with regard to fermentation?—To get yeast we must have fermentation.

19770. Not for the carrying on of fermentation, simply to get a sort of yeast?—The saccharometer shows about 25 to 30 per cent. of spirit more than is obtained by distillation; there must, therefore, be a certain amount of spirit in pot-ale in some form; this we rely upon for the propagation of the yeast.

19771. Is there any fermentable substance left in the pot-ale; any large amount?—Nothing has been found so far to deal with it. Then we have also adopted another system—Dr. Hunter's system. He boils the pot-ale with lime, and then adds the acid phosphate of lime, which produces a clear effluent and a flocculent precipitate, which goes rapidly to the bottom.

19772. (*Chairman.*) We are anxious quite to understand that. Did I understand, Dr. Cowie, in regard to your earlier observations as to the changes which have been carried on at your works since we visited them that you have been adding to the eight contacts a percolating bed?—Yes.

19773. And did I gather further that you found no great advantage after four contacts, because then evils began to arise?—No, sir; I stated that the yeast formed.

19774. Yes, but you obtained alkalinity after four contacts?—After five or six contacts.

19775. Then is it suggested that if for the last four contacts you substitute percolating beds possibly some advantage would arise?—We tried that at my distillery.

19776. And with what result?—The result was not satisfactory at my distillery, but at Dailuaine Distillery they are getting an excellent effluent by continuous filtration.

19777. (*Mr. Power.*) Without any contact previously?—Without any contact previously.

19778. (*Chairman.*) In that case you have some sort of settlement by lime or otherwise?—There is no settlement; they are to adopt this settlement by lime.

19779. In the case you referred to in answer to Mr. Power just now, is there simply the passage of the crude liquor upon the percolating bed?—Upon the percolating bed, yes.

19780. And the results are better than contact beds?—They are there; but I do not find it so in my beds.

19781. In that particular instance fair results have been obtained?—A better result has been obtained.

19782. What kind of a result; was there absence of acidity?—Oh, absolute absence of acidity.

19783. You get a neutral effluent?—A neutral effluent.

19784. And with what reduction of impurities?—(*Mr. Mustard.*) That is a most extraordinary thing; we cannot explain it.

19785. The secretary says you cannot explain it. I would like to know whether Dr. Cowie can say why it has succeeded in that particular case, and not in his own. Is there anything very different in the character of the liquid being dealt with?—(*Dr. Cowie.*) I think the liquor they were using was very much more dilute than the liquor I was passing over my beds; I think that is the secret of their success.

19786. Do you think that dilution would considerably assist the filtration?—I am satisfied that is so, and we are diluting more now.

19787. (*Sir Michael Foster.*) And getting better results?—Better results; yes.

19788. You do not get the growth of the yeast in your percolating beds?—Not so much the growth of the yeast; we have got the sludging tank, which takes it out a good deal. This process of boiling with lime will absolutely destroy all the yeast cells.

19789. (*Chairman.*) That is rather an interesting direction for us to inquire into. The first process of treatment by lime or some other chemical matter has been carried out on a practical scale at your works?—No, at Mr. Thorne's works at Aberlour.

19790. Can he, or will you, give us any data in regard to the results obtained?—He will be able to speak to it, I expect.

19791. Can you, sir, give us the results which have been obtained by first a process of chemical treatment and sedimentation, followed by a process of filtration?—(*Mr. Thorne.*) I have our architect here; unfortunately the director of our company, who has looked after Aberlour, has just died, and although I am chairman I am not so well up in these matters as he was. Our architect, Mr. Doig, happens to be here; I am sure he will be very glad to give the information required at once.

19792. Can you give us the results which have been obtained in that experiment?—(*Mr. Doig.*) I cannot give you an analysis,

19793. Tell us what the experiment is?—The experiment is, first, you boil the pot-ale, and likewise the washings from the tun-room—the yeast washings—and on boiling you add a certain proportion of lime.

19794. (*Sir William Ramsay.*) To the boiling liquor?—To the boiling liquor.

19795. (*Chairman.*) You do not mean boiling with a view to evaporation, simply with a view to heating?—Yes, simply with regard to heating, and afterwards you add a little superphosphate. Then, of course, it deposits very quickly. Then, in about a quarter of an hour, you will have a complete deposit. Then the sludge is taken away, and the supernatant liquor run off and mixed with the steep water washings, and other effluents, and put through a series of contact beds—seven contact beds—six of clinker and one of sand.

19796. With what result?—Well the effluent is very good. (*Dr. Cowie.*) This process, Colonel Harding, has only been going about a couple of months. (*Mr. Doig.*) About a couple of months. (*Mr. Mustard.*) Hardly so much—since January, about the middle of January, so that it really has not, so far, had a long enough trial to enable us to speak very distinctly about it, but we will send you the results.

19797. Does your experience go to show, with regard to the treatment of waste from the distilleries, that it is probably advantageous to first of all treat it in some way with a view to sedimentation?—(*Dr. Cowie.*) That is my opinion.

19798. And then to deal with it over fewer contacts than have hitherto been attempted, or by percolating filters?—I would be inclined to do fewer contacts now from my experience, and put on a percolating filter in the end—a good big percolating filter, I think.

19799. Then are you of opinion that progress is being made in connection with the treatment of these waste liquors by those means?—I am satisfied that that is so.

19800. Are you able to tell us now in regard to the process of evaporation that we then saw? It was suggested to us then that these processes, which, of course, inasmuch as they evaporated the effluents, were perfectly effective from the polluting point of view?—Quite.

19800-1. That these would be successful if it were possible to dispose of the residual matters, the syrup, or the ash. Can you tell us anything further as to whether the hopes that were held out to us in regard to the sale of these by-products have been fulfilled?—You remember seeing, the last works you saw, where they were making the cattle food; that company is now in liquidation.

19802. And what about the Glendullan?—I understand they have considerable difficulty in getting rid of their syrup. There is no outlet for it. I see it lying there in large quantities.

19803. With regard to the ash?—With regard to the ash, Mr. Robertson is here; he will speak of it himself.

19804. What success have you had in disposing of the ash which was produced by the complete drying up of the syrup?—(*Mr. Robertson.*) Well, Mr. Chairman, we had some difficulty; in fact, we still have; but it is a new thing, and it is very difficult to get the manure trade to take it on and look at it, although they are satisfied that there is a beneficial analysis. What we are always met with is the remark, "Well, analysis is not practice." And, of course, we expect to be able to make something out of this, to get some return; but the expense, so far as we have found, of working this evaporating plant will, I think, be prohibitive for the small distillery to undertake it, unless we can show something better than we are now in our return.

19805. (*Sir Michael Foster.*) What is the main composition of your ash produce? What are the striking constituents?—Potash; there is about 5 to 6 per cent. I think about 7 to 8 per cent. of ammonia, and a certain amount of phosphate.

19806. How much phosphate?—From 15 to 16 per cent. phosphate.

19807. A large amount!—Well, we were told by the expert that analysed that it is very good, but when you go to sell the by-product—well, to make a market is the difficulty. We may be able to do that in time, but, as we are only producing a very small quantity at one distillery, it is not large enough to make a trade, if I may say.

19808. (*Chairman.*) You are in the midst of an agricultural district?—Yes.

19809. You say you have not been able to persuade the agriculturists in your district to take this?—Well, we do not get what we consider the full value for it you see; that is our difficulty just now.

19810. You can get a price for it?—Yes, £5 to £6 per ton.

19811. But not a sufficiently high price to make a profit?—I do not say, even though we got the analytical value of it, we would make a profit.

19812. We may take it the amount of this ash is so small there would be no difficulty in getting rid of it at a price, or getting rid of it without selling?—Oh, we could get rid of it. It is not "ash," but dried residue.

19813. And the whole question of cost would turn on the cost of the process itself?—Yes.

19814. Is the process very expensive?—Yes.

19815. You suggest that it is?—Yes, I do, and, knowing what I know about distilling, if a distillery had to go into this process that we have at Tamdhu just now, he would want, what I think Dr. Cowie has emphasised so much in his statement, and which I thoroughly endorse myself, some assurance if he spends £4,000, and, perhaps, on a big distillery like Dailuaine, it would mean a great deal more, if he went in for that sort of thing; he would want some assurance that he was not going to be pulled up over smell through the chimney. We have been hampered in that way.

19816. Well, tell us what your difficulty has been in that respect; have you been pulled up; has any interdict been sought against you?—Oh, no; we have not got that length yet, but we are threatened.

19817. What is the nature of the complaint that has been made?—That we are polluting the air by the smell in drying this residue.

19818. Does it pass into a chimney?—It goes up the ordinary chimney stack.

19819. What is the height of it?—140ft.

19820. And is it alleged that this may be smelt in the neighbourhood?—Oh, yes, it is the complaint of the tenant of one of the fishings on the River Spey that when the wind is in that direction it blows towards his house. That is the complaint made by the Laird which he received from his tenant.

19821. (*Sir Michael Foster.*) Is it in the drying?—It is not in the evaporation, of course, but in the burning We have tried to obviate the burning as much as possible by reducing the heat in the flues. We found that the heat was so great that we were burning it, and if we were burning it we lost so much of the valuable nitrogenuous constituents in the result at the end of the week, and we also made the smell, which, I admit, is objectionable altogether. It is a pretty strong smell, and why it is objectionable I cannot tell you. I do not know anything about the analytical part of it at all. I know that there are certain acids driven off by this heat.

19822. Have you tried various methods of heating and drying, or only one?—What we want to do is to make use of the waste heat from the boiler furnace. Unless we do that there is no advantage. If we cannot use the waste heat, then the process is absolutely no use, because we require so many tons of coal now a week; unless we make use of the waste heat it would take a coal pit. (*Dr. Cowie.*) It would be as well that the Commission should know that coal costs £1 a ton in our district. (*Mr. Robertson.*) Yes, just about that just now.

19823. (*Chairman.*) You have a great deal of waste heat, which you claim you can utilise in drying this?—Oh, yes; the difficulty in taking the waste heat along the flue is to avoid burning this syrup when it is being dried.

19824. You think, then, that the slower drying of the syrup would be better?—Yes.

19825. You are not without hope of being able to accomplish that by experience?—No, I am not, so far as we are concerned.

19826. Then, as regards your process, you have reached this stage that you have ceased to pollute the Spey altogether?—Yes, so far as regards burnt ale.

19827. So far as fishing rights are concerned, nobody can make a complaint of you at all?—I do not know about that. At the last interview we had on this question at the distillery, the remark of one of the riparian proprietors to me was, "Well, you have got on so far, but you have always got the steep water and the washings and the spent lees to deal with, and you will have to deal with these some day." Well, we claim that there is no pollution by these other effluents.

19828. I understand there are two sides to this question; one is the question of the pot-ale, and in that particular case you do away with the effluents and reduce pot-ale to absolute ash; and in regard to the other branch of the work, what are you doing? You suggest that these effluents are not polluting, but probably there is a difference of opinion upon that?—Yes.

19829. But probably those effluents would not offer any insuperable difficulty, would they?—No.

19830. They are very much easier to deal with?—We throw them on the waste ground that we have now; we pump them on; we have to pump them across the railway on to this waste ground, and we let them find their way.

19831. It percolates into the neighbouring ground?—Yes; we have had no complaint of that as yet.

19832. You anticipate that ultimately the effluents will appear in the stream?—No, I do not think so; I do not think it would pollute.

Dr. Cowie.
16 Feb. 1904.

19833. By evaporation you get rid of it?—We could never evaporate these other effluents ; the dissolved ingredients of these matters are so small, as compared to burnt ale ; the polluting value is so small.

19834. At the present moment the result of this percolation, so far as the stream is concerned, is nil ; it does not reach the stream?—It, perhaps, has not had time to come through.

19835. You foresee that it may come through?—Yes, it may appear. We are told by the experts that if we dilute these enough they will never pollute.

19836. Do you suggest that the natural dilution of the stream is the only cure?—That we ought to be allowed to put them into the stream ; our Laird asks us not to do it ; therefore we put it on to the waste ground.

19837. (*Sir William Ramsay.*) Deprived of all the obnoxious ingredients, it may go into the stream relieved of these?—It may.

19838. (*Chairman.*) You think it may reach the stream ultimately, but you think it will be in a safely purified condition?—Yes.

19839. That is what you want us to understand?—In fact, not only so, if we were allowed to dilute that properly and put it into the stream it would not do any harm.

19840. Of the two classes of effluents, clearly the pot-ale is the difficulty ; the other is a minor difficulty which can be met in various ways?—Yes, that is our own opinion, and that is why we went in for evaporation, whereas the others are experimenting—and we are simply experimenting, too, for that matter, because it is a loss from year to year, and a serious one. (*Mr. Mustard.*) It is an establishment involving an expenditure of many thousands of pounds.

19841. I want to ask Dr. Cowie a question or two. You told us just now that the deputation represented the distillers of Scotland, and you spoke to us of the vast capital that was involved in that industry. Has any attempt been made by these associations as such to deal with this question ; has this rich body of distillers engaged any experts to study this matter for them, and to carry out experiments for them?—(*Dr. Cowie.*) Yes, we have engaged experts and paid large fees—several large fees.

19842. Where are the experiments being carried out? Are experiments being carried out at the cost of the association?—Not at the cost of the association. (*Mr. Mustard.*) Oh, dear me, Dr. Cowie, we have paid sums of money over and over again through the association.

19843. For the purpose of carrying out experiments? —Experiments without any result whatever ; do not disguise the thing.

19844. Your secretary says that the experiments which have been made, I understand, at the expense of the association have resulted——?—In nothing.

19845. In showing that nothing can be done?—That is so. (*Dr. Cowie.*) That is so.

19846. But do you suggest to the Commission that that is the result of the experiments which, either on behalf of these distillers as an association or on behalf of individual distillers, have been carried on, that they have given no better results?—That is so.

19847. That there is no hope whatever of dealing with this matter?—I do not say no hope

19848. (*Sir Michael Foster.*) Then do you think we can deal with it ; do you think that our experts can do what your experts have failed to do?—Well, we think we can get a good deal of guidance from you.

19849. But surely we are misunderstanding each other, are we not?—We must be, I think.

19850. (*Chairman.*) You said some of the experiments you had undertaken were rather promising?—Yes.

19851. Your secretary tells us that all these experiments which have been carried out on behalf of these associations have been utter failures?—(*Mr. Mustard.*) That is so, Mr. Chairman ; on behalf of the association, but Dr. Cowie told you outside the association.

19852. We are to understand that whereas the association experiments have failed, individual experiments in certain cases have proved hopeful?—Exactly. What Dr. Cowie told you about was not an association experiment.

19853. Then I return to the question of the association ; as it appears to us—or to me, I do not speak for my colleagues in this matter—it does appear to me that where you have an exceedingly powerful organisation of this kind, and where you have a difficulty to deal with, which is at once very great, and which you all keenly appreciate, that clearly some attempt ought to be made by the distillers as a body to endeavour to solve this difficulty for the benefit of the individual distillers ; has nothing been done?—(*Dr. Cowie.*) Well, all those works are being put up and worked, you know.

19854. But are they worked at the expense of the individual distiller?—At the expense of the individual distiller ; but we have had advice from eminent chemists, to whom large sums have been paid by the association as an association.

19855. The suggestion, I gather, is rather that this Commission should employ its experts to find out for the Distilleries' Association what is the best way of dealing with these matters?—Well, the suggestion that we have come here to make is that we should get an official pronouncement of what is the best possible means of dealing with our works ; that you should make these observations on the same lines as you are at present doing at the various stations in England. I understand that at present you have certain places under observation in England.

19856. Yes, just as we have under observation the various experiments that you are carrying out on the Spey?—Yes.

19857. But I am afraid this Commission cannot recognise as part of its direct business that they shall tell the distillers the best way of carrying on their business. We are prepared to investigate these processes, and to see which of them show advantages and which do not, and to express an opinion at the close of our investigations ; what I think I feel in the matter is that the main business lies with the distillers themselves to find out a solution of their difficulty. Any assistance that this Commission can give them they will readily give, but the main business must be carried out by the distillers themselves?—We are carrying on these experiments at present. There are several new processes being tried since your last visit. Mr. Russell Duncan has a plant at Craigellachie Distillery ; there is also an oxi-chloride process being tried.

19858. (*Sir Michael Foster.*) At the instance of the individual distillers?—At the instance of the individual distillers.

19859. I rather conclude from what you have said that the money which the association has spent has been rather the payment of fees for advice to eminent chemists than for direct experiments in this case?—That is so.

19860. What Colonel Harding was inquiring was whether these associations had not carried on experimental investigations of the kind that you are asking us to do?—Well, I only wanted you to come up and observe and see, and report on what we were doing. We do not come here asking you to make experiments for us ; and if your experts suggested any experiments every distiller would be only too willing to carry them out at his own expense. We do not ask you to do anything of that sort ; we simply come here asking for advice and guidance.

19861. (*Chairman.*) I think we gather then, generally, from the information that has been put before us, that the distillers are now perfectly aware that they must make an attempt to reduce the pollution, that they are making serious attempts in various directions, some of which are at present fairly hopeful ; apparently, they think a certain time must be given to them to carry out these experiments ; is that the position?—That is the position.

19862. (*Sir William Ramsay.*) I understand Dr. McGowan has been corresponding with you?—Yes.

19863. And he has been producing a perfectly good effluent by liming the pot-ale and filtering it?—Yes.

19864. Could that not be tried on a large scale to see if it will work as admirably as in the experiment?—That is being tried.

19865. By yourself?—No. Well it is practically the same thing at Aberlour. After the pot-ale is boiled with lime till it is faintly alkaline, then the superphosphate of lime is added till it is faintly acid.

19866. It does not boil?—It is discharged from the still at nearly boiling point. If you try the experiment

with pot-ale you will find it comes down much more rapidly, and that the precipitate is much heavier than that produced by adding the milk of lime alone.

19867. It is costly to boil it; it runs out hot?—It only requires a little steam to boil it. It is discharged from the still at a temperature of about 190 deg. to 195 deg. Fahr.

19868. You would not let it cool?—Simply pump it direct into the precipitating tank, add ground lime to faint alkalinity, and then neutralise with phosphate of lime.

19869. Phosphate and boil?—Yes.

19870. Would it not be possible to get that plan adopted all round, because it is an obvious one?—Well, we want a little time to see how these things would do. That is the view of the gentlemen here; as it is, we are being forced at the present time, and we have got to an *impasse*.

19871. Speaking on that subject, the judgment of the Court appeared to be that you had had a considerable amount of time to look round you; the judgment was based on the fact, was it not, that you had had four or five years?—Well, that is so, I believe.

19872. (*Major-General Carey.*) Practically nothing had been done?—In that particular case. The other cases in which they are being attacked; for instance, in this case Mr. Robertson has told you about, they have spent £12,500 in this evaporator process experimenting; now they are likely to be shut up, because they are polluting the air. We do not know what to do.

19873. (*Mr. Power.*) Have the associations employed experts to pronounce on the relative value of the experiments the various distillers have carried out, or is each one left to experiment himself, and judge of the value of the effluent himself?—Experts have been sent down by the Court in various cases, and we have seen their reports to the Court.

19874. To see whether or not they satisfied certain conditions?—Yes.

19875. (*Sir William Ramsay.*) They do not give you any advice what to do?—The great trouble is, we cannot get any indication from the riparian proprietors as to what they will be satisfied with. They say, "We want you to put back pure water into the stream," and anything short of that they will not accept.

19876. (*Sir Michael Foster.*) Do I understand, Dr. Cowie, that either as individual distillers, or by means of the Association of Distillers, you are prepared still to carry on experimental investigations, with the view to seeing if your processes can be improved?—Most certainly.

19877. You are prepared to spend a good deal of money on that?—Most certainly.

19878. And all that you are asking the Commission is that, by means of our experts, we should from time to time give you, after inspections, criticisms and suggestions?—That is what we come here for.

19879. You do not wish us to carry on the investigation?—No, certainly not.

19880. (*Mr. Power.*) Have you any reason to think that if very serious experiments are carried out, with the view to meeting this difficulty, time would not be given you by those who are opposing you at present to obtain these results from these experiments, and possibly the report of the Commissioners thereon?—I think it would be only reasonable that these gentlemen should do so, if the Royal Commission asked them, and they were satisfied that these experiments were being carried on seriously, and that you were prepared to report, say, next year.

19881. (*Sir William Ramsay.*) And you suggest that the riparian proprietors should be asked to confer with the Commission in regard to the whole matter?—Yes.

19882. (*Major-General Carey.*) Has the action of the riparian owners been directed against all distilleries whether they are doing anything, or whether they are doing nothing?—Oh, yes, against all distilleries.

19883. (*Chairman.*) There is just one point, Dr. Cowie; do you know anything about certain experiments, either suggested or actually now being carried out, by Dr. Russell Duncan, at one of the distilleries at Craigellachie?—I understand that he had a demonstration the other day on a small scale in Elgin, and I understand that at present there is some little hitch, that his machinery is not ready. We had hoped to have had Mr. Mackie, at whose distillery that experiment is being carried out, present here to-day, but he has not been able to come.

19884. Have you any knowledge yourself of the process, or are you at liberty to tell us?—I have no knowledge personally, but I hear he finishes up by electrolysis, and that he adds lime, and some other salt, and filters through some film that is produced.

19885. At present neither you nor any of the gentlemen are able to say anything about the experiment?—(*Mr. Robertson.*) I have seen the plans of his machinery, but I am not sufficiently expert—I might be able to answer some questions upon it, but I could not describe it.

19886. We will not endeavour to get any information upon it until the experimenting is in a more forward state?—I think, in Craigellachie, he has not begun to run yet, but they are taking it up very seriously. The directors are certainly going to give him every facility. They do not object to spend money in order to try and arrive at the practical outcome of this process, but I cannot explain the process, though I have seen it.

19887. (*Mr. Power.*) Is the experiment on something more than a laboratory scale; is it on a large scale?—I understand it is to cure the output of the distillery altogether. He has done it under certain guarantees, and the distillers have granted him several amounts, I understand.

19888. (*Sir Michael Foster.*) At the expense of that particular distillery?—They have granted him certain expenses, and they will pay him so much if he will cure; I do not know what the arrangement is, but I know it is a mutual arrangement between them.

19889. (*Chairman.*) Then, probably, much of the difficulty, Dr. Cowie, has arisen in consequence of the distillers having for a long time not recognised the necessity for dealing with their waste products?—Well, I think it was in 1896 that the question first came before distillers, and the history of the thing was this: Distillers were then asked by riparian proprietors to do something, or they were told that they must carry out the provisions of the Public Health Act or the Rivers Pollution Act, which stated distillers should dig pits on their own ground, or as near as possible, for the settlement of the stuff before running it into any ditch. That was done. That would be about 1898. Everybody had these sand-pits. The result was most disastrous. Whereas the burnt ale being put into the stream does not produce *leptometus lacteus* to any extent, this stuff, in percolating through the sand, although perfectly clear, had a most acid, acrid stench, and the streams were covered for miles down with this *leptometus lacteus*. Then it was obvious that would not do. The next thing was what was to be done with that; so we began experimenting on various lines. That experiment that Mr. Robertson has been talking of has been going on, I think, since 1899. (*Mr. Robertson.*) Yes, 1899. (*Dr. Cowie.*) Since that time I have been experimenting on the other line, and, of course, it all takes a little time, and you have to turn round so often; but I may say this to the Commission, that at every turn we have been driven further and further. The screw gets another turn, and we are now getting so tightened up, that we are at an *impasse*. You see from what you have heard to-day, that if you put the stuff into the stream without making it absolutely pure water, you are immediately attacked; if you put it into the air by destruction it creates a smell. Then the landowners immediately say, "You are polluting our grouse moors, and we cannot have that." It is also very difficult for a manufacturer situated as I am, or as Major Grant, of Glengrant, in Rothes, to put up a plant of that sort, because of the smell coming across the village you will have interdicts fired at your head from every quarter. It is not as if we were in a city where there is a number of chimneys and a number of smells, such as Manchester, but we are out in the country in pure air, and any little thing like that soon attracts the notice of anybody who happens to come along.

19890. (*Sir Michael Foster.*) I rather gather, Dr. Cowie, that no very distinct effort has been made to modify in any way by any contrivance the smell which comes from burning?—They have tried in every way possible by putting on subsidiary furnaces to modify this smell, but, so far, without any very satisfactory results. (*Mr. Robertson.*) We do not want to burn the stuff; we lose weight. We want to dry it. This is entirely new.

Dr. Cowie.

16 Feb. 1904.

19891. The smell is in the drying?—In the drying. If it is burned there is a smell, but there can be no objectionable smell if you can regulate the drying and heating process, and that is the experiment we are making.

19892. (*Chairman.*) No difficulty arises in the first evaporation process, reducing the waste products to the condition of syrup?—Yes, burnt-ale entirely; we are not treating of these.

19893. Up to that point no difficulty arises?—None whatever.

19894. The steam arising does not cause smells; it is the final burning up of the syrup?—Yes; we are drying in vacuum, reducing in vacuum to syrup.

19895. (*Sir Michael Foster.*) It is the drying process previous to incineration?—Well, we have to run the syrup out into a vat.

(*Dr. Cowie.*) To make it a manure.

(*Mr. Robertson.*) We run it on to pans, and then run it on into a flue and let the heat pass over it; the waste heat from the furnace for driving the evaporators, heating the evaporators.

19896. (*Chairman.*) No evil arises from the first evaporation?—None at all; none whatever.

19897. Have you tried experiments for the slower drying of the stuff into solid matter?—Yes. I think that means room, because the heat comes into the flue at a certain degree which would burn at once. We have to carry the flue a long way, and then put into the flues. To dry that means room—a shed—an expense.

19898. I admit these experiments at the expense of individual distillers are very serious things indeed?—They are indeed; I can speak for ourselves.

19899. The distillers of Scotland do not recognise the advisability of forming a fund to carry on on their general behalf serious experiments in this direction?—Yes, of course they are all doing something.

19900. (*Sir Michael Foster.*) That, I gather, has not been done?—One distiller says, "That is the way to do it"; another says, "Well, I know it can be done in this way, if I just get enough time to carry out my experiments." Therefore it would be a little difficult for them to combine under these circumstances. (*Mr. Grant.*) Every distiller is so differently situated; it is impossible for distillers to combine to do things like that, because every distiller, owing to the situation of his distillery and one thing or another, must carry out really his own arrangements. If the distillers were all together we could easily combine, but we are all differently situated on different points.

19901. (*Chairman.*) Well, we can only gather information on these points. We can only take for what it is worth your statement that such a combination is not possible?—I do not think so. (*Mr. Robertson.*) Take a distillery like Ben Rinnes, which is six miles from a station—I am not quite sure, but the mileage is very serious; if they were to undertake evaporation, say, on the process that we are doing, well, the coal costs £1 now in order to get to Aberlour, and it is up hill the whole way. I do not know what it would cost at the other end; anyhow they would hesitate to evaporate; they would have to use perhaps 10 tons a week, and they are only getting 3–5 tons of bye-product.

19902. I think, Dr. Cowie and gentlemen, it is not necessary to detain you further. The Commissioners have listened with much interest to the facts which you have put before them. It will probably be possible for the Commission to hear what the riparian owners may desire to put before them, and they will then have to consider the whole matter?—(*Dr. Cowie.*) I have to thank you, Colonel Harding, on behalf of the deputation. (*Mr. Mustard.*) Excuse me, Mr. Chairman; there is one thing, which is a very important thing—if we can get a standard of purity fixed for our effluent, suppose we get 90 per cent.; we could purify up to 90 per cent. if we could put into the stream at 90 per cent.

19903. Do I understand you to say that it would be a facility to you if some standard could be named?—Most certainly; and mind you, Mr. Chairman, we are probably the most important manufacturers in Scotland. We cannot put that to you sufficiently strongly. We pay £15,000,000 to the Revenue every year— to the Imperial Revenue; you cannot forget that.

19904. Yes; but what really interests us is your observation, Mr. Secretary, and that is this—that you think it possible to purify to the extent of 90 per cent.?—We can purify up to 90 per cent., but we cannot put it into the stream exactly as river water—it is impossible; and if we are not allowed to do it we have got to stop our business.

19905. The statement you make to us I take to be official, made in the presence of so many gentlemen?—That is so.

19906. That you can see your way to purify your effluents up to 90 per cent.?—That we can see our way to purify our effluents up to 90 per cent.; is not that so, Mr. Doig?

19907. I did not gather that from the answers.

19908. (*Sir Michael Foster.*) By which of the various processes—by all of them?—No, I told you one—lime, phosphate of lime, and boiling up to 212 degrees, the bacteria beds, putting it through beds; that is the best effluent ever I have seen.

19909. (*Chairman.*) A chemical settlement following upon boiling?—Boiling up to 212 degrees.

19910. And then passage through bacterial beds?—No, that after; through lime, superphosphate of lime, and bacterial beds, and you will have over 90 per cent. of purification.

19911. (*Sir Michael Foster.*) I think your point, Mr. Secretary, is this—that if by any of the processes it can be shown that you can achieve a purification of 90 per cent., the riparian owners ought to be content with that, and not insist on absolute purity?—That is so, and for goodness' sake let us have a friendly interview with them and keep us out of the Court of Session.

19912. (*Chairman.*) Are we really to take it from you that you can so deal with it as practically to reduce the impurities to 90 per cent.?—Yes, we can.

19913. And that the distilleries are prepared to undertake the expense that may be necessary to obtain that 90 per cent.?—I cannot guarantee anything. (*Mr. Robertson.*) In connection with burnt-ale, of course, I can safely guarantee this percentage.

19914. (*Sir Michael Foster.*) Is Dr. Cowie able to guarantee a purification up to 90 per cent.?—(*Dr. Cowie.*) I do not quite understand what 90 per cent. of purification means. I am not prepared to answer the question.

19915. (*Chairman.*) You are referring to burnt ale?—Burnt ale, certainly.

19916. I take it in regard to the other difficulties, the difficulties would not be greater, but less?—(*Mr. Robertson.*) Oh, certainly; that is, our own experiments have led us to come to that conclusion. (*Dr. Cowie.*) In this process that Mr. Mustard refers to, you add all your other effluents to cool the liquor—the supernatant liquor there, after precipitation.

19917. (*Sir Michael Foster.*) So that when you are dealing with burnt ale you are dealing with everything?—(*Mr. Mustard.*) Dealing with everything; you would require to use all your other liquors to cool your boiling liquor.

19918. (*Chairman.*) Where is your experiment being carried out?—You will see it at Aberlour, and you will see it at Mr. Thorne's place, but we have not got the heating into Dailuaine just yet, but it will be in a fortnight.

19919. Then you are not able as yet to give the Commission any definite data in regard to the result?—(*Mr. Mustard.*) We will give you the samples, and I will guarantee to give you them within a week. I think at Dailuaine we must be precipitating up to 90 per cent.; precipitating in the tanks; this boiling process is simply to ensure that precipitation.

19920. You are satisfied from your knowledge of these experiments that you can reach the 90 per cent. degree?—We believe our effluent is absolutely innocuous, but we do not know whether our opponents are satisfied or not; they will not express an opinion.

19921. But you have 90 per cent. of purification?—Yes.

19922. And you are prepared to spend money to get that 90 per cent.?—We are prepared to spend any money.

19923. (*Sir William Ramsay.*) Is there any market for your sludge?—We are not precipitating by that process at present. (*Dr. Cowie.*) Like the recovery process, it is very easily dried, this sludge, and should be worth something, but the thing is too new to speak much about it. The difficulty is that time is required. I have to thank the Commission for their courtesy in seeing us so early, and giving us such a patient hearing.

SIXTY-NINTH DAY.

Tuesday, 10*th May*, 1904.

PRESENT:

The Right Hon. the Earl of Iddesleigh (*Chairman*).

Sir William Ramsay, K.C.B., F.R.S.
Major-General Constantine Phipps Carey, C.B., R.E.
Colonel T. W. Harding, J.P.
Dr. James Burn Russell.
Mr. T. J. Stafford, F.R.C.S.I.

Mr. F. J. Willis (*Secretary.*)

ALSO PRESENT:

Dr. A. C. Houston.
Dr. George McGowan.
Mr. G. B. Kershaw.
Mr. C. C. Frye.

The Duke of Richmond and Gordon, Mr. John R. Findlay, Mr. W. S. Menzies, and Mr. J. H. W. Grant, called in; and Examined.

The Duke of Richmond and Gordon, Mr. John R. Findlay, Mr. W. S. Menzies, and Mr. J. H. W. Grant.

10 May, 1904.

19924. (*Chairman.*) My Lord Duke and gentlemen, In the first place, it is our duty to thank you very much for your kindness in accepting our invitation to come before the Commission to-day, and I should wish to explain that a part of our reference imposes upon us the duty of investigating the disposal of trade effluents, and that our attention having been called to the question of distillery refuse in Scotland last year, some of our members visited Scotland, and, as a result of the visit, we came to the conclusion that the question was one of magnitude and difficulty, and that a great deal of consideration on our part would be necessary before we could make any report on the subject. Well, this consideration we shall undertake as soon as we possibly can; that means, as soon as our officers are free from the occupations on which they are at the present moment engaged, and which we cannot very well interrupt. The next thing that happened was that early this year we received a request from the Scotch distillers that we would receive a deputation on their behalf, who would be able to lay their views before us, and to this we agreed, and I believe that the report of what passed at that deputation has been sent to you?—(*Duke of Richmond and Gordon.*) Yes, we have had a copy.

19925. We understand that the position that the distillers take up is that no one knows at this moment what the best practicable means of purification are, but it is hoped that our investigations may settle this question, and the distillers argue that they should not spend money now in large amounts, because that money may prove, in the light of possible further knowledge, to have been thrown away; in fact, to put it shortly, as far as I can make out, what they want is that the present state of things should be allowed to continue until our investigations have been completed, and we have reported what means are available and practicable for the purification of this refuse. In the meantime, they propose, at least I presume they do, that they should make such temporary arrangements as are necessary. Also, I understand that they are quite willing to carry out any experiments that we may suggest, and it is by their request that we have ventured to approach you. I can only again say that we are very much obliged to you for your kindness in coming here, and that we shall listen with the greatest possible interest to any views that you may place before us?—(*Duke of Richmond and Gordon.*) Perhaps I should say, first of all, that Sir Charles Logan (who represents the Countess Dowager of Seafield) and Sir George Macpherson Grant are unable to attend. They are neither of them very strong. I saw Sir George yesterday, and he said he would come if he could, but when I saw what the morning was, I felt convinced that he would not be able to come. Sir Charles Logan and I have been in correspondence, and I am justified in saying that although they are not here, they are cognisant of my views, and are entirely in accord with them; so I think you may take it that although there are only four out of the six who were originally invited, they will confirm and stand by any statements that we make to-day. Well, then, first of all, perhaps it would be as well if you told us to what extent you want evidence from us as to the spawning facilities that exist on the Spey; I mean, whether you wish us to go into a description of the river, or simply to deal with the matter, taking that for granted that there is fishing in the Spey, and that spawning beds are a necessity to continue the breed, whether you wish us to give you any account of the condition of the river, or whether you simply wish us to deal with the statement put forward by the distillers, of which we have all had a copy.

19926. I think we may take the state of the river for granted. Some of our Commission have visited it?—I believe some of the Commission have been north.

19927. Yes?—Then, of course, the condition of the river, the formation of it, the spawning beds, and so forth, that, as a matter of fact, nobody can gainsay. Then there are one or two points that Mr. Grant would perhaps like to deal with himself, as they have occurred on his water; Mr. Findlay, too, has one or two spawning beds, which he would like to mention, which he has been more immediately concerned in than I have; but I may say generally that the negotiations with the distillers first commenced some years ago. I forget the actual date of the first communication that passed between the proprietors and the distillers, but it was some ten or twelve years ago—something of that sort; I would not be sure of the year, but if you wish for that I can get all that for you.

19928. Oh, no?—Then I need not go into detail, I daresay, of the number of distilleries which are on the river now, or the bushels of malt that they deal with every week.

19929. No?—But I may make a general statement, that within the last ten or twelve years the number has enormously increased. Possibly some of the Commissioners who have been up there have got all those facts, but I think I cannot be too strong in pressing the fact that the increase has been beyond anything that was dreamt of. Well, there is a tributary of the Spey, the Fiddich, which runs to a great extent through my property, and some years ago that was one of the best spawning beds in the district; the fish went far up—I have got a shooting lodge there—900ft. above the sea, and the fish used to go and spawn there and beyond, winter after winter; they used to get as far up into the little river not much broader than this table; some of you may have seen. Well, now there is not a fish, there is not a fish of any sort or kind comes up there. When they leave the Spey, about the point of leaving the Spey, they are met face to face with this enormous mass of pollution, which comes out of the Fiddich itself, and the condition of the Fiddich itself—I should have liked some of the Commissioners to have seen it in the summer time, in the spring time at any rate, when the water is low, the condition of absolute filth to which the distillers reduce it—slime and fungus through it from side to side. I am surprised that any fish get through it at all. Of course, when you get a heavy water or a big spate, or anything of that sort, this pol-

The Duke of Richmond and Gordon, Mr. John R. Findlay, Mr. W. S. Menzies, and Mr. J. H. W. Grant.

10 May, 1904.

lution gets to a certain extent diluted. There is a certain number of fish who will force their way through, but I do not think I am over-stating the case in saying that there is not one fish in the Fiddich now to fifty that there were ten years ago.

19930. And the refuse discharged into your river has increased beyond all expectation?—Oh, yes, distillery after distillery went up. I suppose there is some special quality about the water there, which enhances the quality of the whiskey, and they came dropping down there one after another. Mr. Grant reminds me that not only the new ones arrived there but the enormous additions that were made to the buildings and the producing power of the old ones. Well, I mentioned the Fiddich first, because I am more directly concerned in that as a spawning bed, but you may take it the same condition prevails on the Spey beds, especially on Sir George Macpherson Grant's property and on Mr. Findlay's, and on Mr. Grant's and on Lady Seafield's waters. Those are all above the Fiddich, and Sir Charles Logan would have told you, but Mr. Grant will tell you, that the spawning beds on his property used to be notorious for holding spawning fish in the breeding season, and now the difficulty is to find a pair there at all. Well, I should like to mention a point—certainly it is only inferential you may say, but I think it is not an unfair inference to draw—that fish will not face this enormous mass of pollution which comes down the river. In the last few years the number of fish that spawned in my water—that is to say, the last seven or eight miles of the river down to the sea—has enormously increased. I could not tell you the actual increase, but you will see the spawning beds. There are fish now which spawn down to within a quarter of a mile of the tide, which comes a little way into the river. It does not really come into the river, but it rather backs the river up. Well, the number of fish which spawn down in the lower reaches now is far in excess of anything that was there before the pollution, and this increase has been contemporaneous with the increase of the distilleries and the consequent pollution which they put into the river; and I do not think it is an unreasonable inference to draw that the fish find the river in such a state that their nature rebels against trying to force their way through all this pollution, and they have stopped and spawned in the first place that they can. There is an idea that you cannot make good whiskey in hot weather, but, at any rate, distilleries must shut down for a certain time in the summer for cleaning out purposes, and then they start full blast immediately after the harvest, when the first of the barley crop becomes available, and I suppose the distilleries are worked at their heaviest about the month of November, and that is the time in ordinary years there is a very large number of fish which would be trying to force their way on up to the spawning grounds. Consequently, those fish which now spawn down below are the fish which, I think, if the river was in the proper condition, would have gone further on. And I may mention, too, that with regard to that—of course, I know it is not a very strong argument, this one that I am putting forward, but I think it is a fair inference to draw as suggesting the amount of damage that pollution does—I should say that the spawning beds on the lower reaches of the river are far less productive for the number of eggs deposited than those higher up. And for this reason: that the lower pools of the last three or four miles of the river are much shallower, the whole bed of the river down there is very much higher up than it is further up the river, and there are no retaining banks—the river may be here to-day and 150 yards further east or west in a couple of months' time, and those lower spawning beds are very much more liable to damage for that reason from spates than those further up the river. I should like the Commission just to take a note of it, although I admit the argument is not a very strong one, perhaps, but I think it is a fair inference to be drawn. Then there is no question but the pollution of the river affects the rod fishing. I do not go so far as to say that it will kill mature fish, but from the experiments that we have tried it will kill the young fish, the fish shortly after they are hatched. It kills them. I think you have a case quoted here? (*Mr. Grant.*) Yes. (*Duke of Richmond and Gordon.*) We have carried out experiments taking specimens of the water from below the distilleries, from below where the distilleries put them in; we have taken that down to our hatchery, where we hatch out about 800,000 or 900,000 eggs every year, and putting the young fish in, in some cases they died after two or three minutes. It is not a question of the water which we took having been kept and have staled in any way, but it has been taken at once from the river to the hatchery, the young fish have been taken out, and there they have died right away; they made no effort, and if that happens in such a case as that, I think it stands to reason that the same process must be going on wherever there is a spawning bed in the vicinity of an output from a distillery. Well, if any of the Commissioners were fortunate enough to see the deposit that is left from the pollution which is put in by the distilleries I think that they would be very much astonished; I am not aware that any of them have, but down below me—and I am seven miles, I suppose—the point I am speaking of is some six miles, at any rate, from the nearest distillery—you see the stuff coming down the river, and it will settle in eddies, and wherever there is a slack corner, and wherever the river goes back, it leaves a foul black slime. Now that happens miles and miles, mind you, six miles away from the nearest point where it is put into the river, and that must be surely far more deleterious in the neighbourhood of the distilleries than it is at the point I am speaking of. It comes down in various shapes, in various forms; I have no knowledge of chemistry, so I cannot explain the component parts of it, but it comes down in various shapes and forms; it comes down sometimes in the shape of a white froth, and many, many times when I have started out on the river fishing I have arrived there, and I have said, "Well, it is no use fishing to-day; the river is white from side to side;" you see the river covered from side to side with patches of froth, and in some cases froth coming down in pieces as large as a hat-box, for instance.

19931. (*Sir William Ramsay.*) Are you speaking of the Spey or the Fiddich?—The Spey, oh, yes; and was just going to say——

19932. (*Colonel Harding.*) Is the observation of the Duke referring to the present time or some distant time?—Oh, last autumn and this spring. (*Mr. Menzies.*) This spring too.

19933. This is a recent observation?—Yes, this spring. (*Duke of Richmond and Gordon.*) I can guarantee you can see it there to-day. (*Mr. Menzies.*) I am sure you could. (*Duke of Richmond and Gordon.*) But I am not putting this forward merely on the sporting ground; it is a far more serious matter to us than the fact that I or my three friends here are not able to enjoy a day's fishing ourselves. A continuation of this is bound to have a very serious effect upon the value of our property. There are many people who are fond of salmon fishing, and who will give a good deal of money for it, but if this condition of things on the Spey is to continue, unless something is done it must get worse, and the value of our fishing properties will be very prejudicially affected. And on that point I may say that we feel rather sore about this, because we have had to spend for some years past, year after year, very considerable sums of money—for what? Simply to preserve our property to ourselves, the injury to which is being caused by the distillers who have started all these enormous works, and we were there before they were, and our contention is that they have no right to come down and not only injure our property for the moment, but it is a thing of this sort, if some check is not put upon a thing of this sort, the permanent value of the place will be more prejudicially affected than it is for the moment, because as the pollution goes on the river gets worse and worse, and worse and worse, and the prospects of any value attaching to it become more remote. It is mainly on those grounds that we complain of the pollution being put into the river. I think your Lordship said—I understood you to say—that later on your experts were going to take up the actual question of the component parts of the pollution.

19934. (*Chairman.*) Quite so.—So I need not bother you with that. Well, then, the point that we feel strongly upon is this, that we have been, we consider, patient beyond words in the action that we have taken against the distillers. I told you when I began my remarks that it was some years ago that we first took any steps, and we have been met by various pleas put forward by the distillers. Some of them have said, "Oh, we are very sorry that we are polluting your river; we do not want to do you any harm; nothing is further from our wish than that." Well, that is very well as

far as it goes, but that is where they stopped. Well, then, again there are some who admitted they were polluting the river, and maintained they had a right to do it. Others, again, said, "Well, we will see what we can do; perhaps we can do something;" but nothing in the way of asperity on our side has ever entered into any of our communications with the distillers. Perhaps you would like me to tell you the process we have adopted in our dealings with them, how we have set to work?

19935. Yes, we should.—Well, we saw in the early days that this was going to be a very serious question, and we put the matter into the hands of our Edinburgh lawyer, and all these distillers have from time to time been written to. We have taken samples of the effluent coming from their distilleries; they have been written to; their attention has been drawn to the fact that they were putting pollution into the river, and various replies and correspondence have passed between us and them. They have asked—those who really wanted to do something have asked for time, and said they would try and see what they could do, and time has always been given to them. It is only in two cases, where we saw that that could not go on any longer, that we took them into the Court that we have done so. There is one case, the first case, which was against a man named Kemp, in the Maccallan Distillery. There we succeeded, and he now has put in certain remedial works. Well, it is close to you, Mr. Grant; you know better than I do what the condition of the burn is. (*Mr. Grant.*) It is much improved.

19936. It has been much improved?—It is not on my property. (*Duke of Richmond and Gordon.*) The Maccallan. (*Mr. Menzies.*) It is very small; they put it all on land; it is a very small distillery. (*Duke of Richmond and Gordon.*) We have never threatened them needlessly; it is only when matters have become so serious that we saw the only course we could adopt to preserve our property was to take them into the courts, and we had an action against Kemp, of the Maccallan Distillery, and we were successful; and we have had another action, in which we got an interdict against the Daluaine Distillery. That is on Mr. Grant's property, and another one further up the Spey, on Sir George Macpherson Grant's property. As a matter of fact, I should say that the Daluaine people are not satisfied with the decision of the Court of Session in Edinburgh, and they now propose taking it on to the House of Lords.

19937. You say that possibly one of these cases is going to the House of Lords?—Yes.

19938. And that will be the first time the House of Lords has had a case before them?—Yes; the decisions of the two Courts in Edinburgh have been in our favour, and the distillers are not satisfied with them, and they propose to take it on to the House of Lords. I think those are generally the principal points which you would wish to be informed upon, and, if you like, I might make one or two remarks on some of the suggestions put forward by the distillers.

19939. Might I just ask you two more questions?—Certainly.

19940. In the first case you mentioned, in which proceedings had been taken, the distiller, I understand, took steps to remedy the mischief?—After we got an interdict against him.

19941. Yes; but are those steps satisfactory; that is to say, if such steps as these had been taken generally, would that probably have solved the difficulty?—Well, I would not like to go so far as that. You see, it is not a very large distillery, and he has facilities for disposing of his stuff, which come easier to hand than in the case of the distilleries which are malting a very much larger quantity. It is partially successful. I think it is simply a question of time really how long his will last. (*Mr. Findlay.*) At present the burnt ale is all carted away; it is pumped up into a big tank at the top of the hill, and there are several farmers round about to cart it away. As far as the burnt ale is concerned, I understand there is no process of purification adopted. (*Duke of Richmond and Gordon.*) It is simply removal, complete removal.

19942. In the case to which your Grace referred, where you noticed the stuff coming down to a distance of six miles, I suppose the refuse would be turned straight into the stream without any treatment at all?—Except in one or two cases, it has had no treatment at all anywhere yet.

19943. The treatment is rather the subject?—There are three or four distilleries at Rothes; there is one very large one belonging to Mr. Grant, not this Mr. Grant, but Mr. Grant who was before you the other day, and there the whole of the effluent from their distilleries comes straight into the Spey through the medium of the drains of the Burgh of Rothes.

19944. Without any treatment at all?—Yes, they have rather got—the distilleries there have rather got the best of the Burgh of Rothes. When the Burgh of Rothes put up a drainage system of their own, they originally did not contemplate—I think it is the bacterial system there—having to take all the refuse from the distilleries. The distilleries were a valuable asset to the town of Rothes, because they were very highly rated, and they found that they could get the use of the Rothes drains; consequently—well, I presume this is the fact—they said to themselves, "What is the use of our putting up remedial measures at our distilleries? Rothes drains take what we put away; Rothes are the people to purify." The consequence is, the whole of the pollution from these distilleries goes straight to the Spey. Whatever purification they have got at Rothes is no use at all; it is a farce.

19945. Any purification is rather the exception than the rule?—(*Mr. Menzies.*) Entirely the exception.

19946. In the present state of things, purification is rather the exception than the rule?—(*Duke of Richmond and Gordon.*) Oh, yes; and where it has been tried I quite admit that the distillers have had some difficulties to face, because absolute purification is very difficult to achieve; there is no doubt about it; but where we feel so strongly, is that they have taken so little heed of all our early representations. In some cases they have put up settling tanks; they might just as well have put basins for all the practical use they are, in taking away anything but an infinitesimal portion of what was coming from the distilleries, and it was not until they saw that the law was on our side that any of them really took up the question earnestly, I believe, then, with the desire to see what they could do. It may be an expense to them, but, as I said a little while ago, it has been a great expense to us to preserve—endeavouring to preserve, for we have not succeeded in doing it yet—in endeavouring to preserve our property, and if we have had to spend money doing that, they ought to spend money to do it on their side.

19947. Then, may I ask whether the number of fish have diminished within the last ten years?—Oh, on the upper waters, yes, but in the lower waters, where the pollution becomes more diluted, the falling off has not been so marked, but that tallied with what I told you just now about the inference I drew from the number of fish spawning lower down.

19948. Would the number in the lower waters be actually increased, do you consider?—No; I beg your pardon, I do not quite understand.

19949. Well, as far as I understood, there are more fish spawning in the lower waters now than formerly?—Yes.

19950. And would that actually increase the number of fish caught in the lower waters?—No; the number actually caught with the nets in the lower waters remains about the same; it has averaged the same for a good number of years.

19951. And the number in the upper waters has decreased?—Has decreased; oh, yes, that I admit.

19952. (*Major-General Carey.*) Is there any record of the number of fish taken annually on the Spey?—Yes; my net fishing is recorded.

19953. I mean the upper reaches?—I should think everybody——(*Mr. Menzies.*) I should think everybody has books; all your country and mine any way; it has gone down to nothing virtually.

19954. (*Chairman.*) Does the state of the river vary much; does the fact of the shutting of the distilleries in the summer produce any appreciable result on the state of the river?—(*Duke of Richmond and Gordon.*) Does what?

19955. Does the river appear to be less polluted when the distilleries are shut?—Oh, yes.

19955*. Very much less?—If you were there in the month of August, a good many of them are beginning to shut down now or about the 1st of June, but June, July, and August, then there are a few of them, working there may be some who have got a

The Duke of Richmond and Gordon, Mr. John R. Findlay, Mr. W. S. Menzies, and Mr. J. H. W. Grant.

10 May, 1904

large amount of orders, begin making early in July, but, as a rule, it is the end of August or the beginning of September or even later before much work goes on, and if you are on the river in that time of year, you will see she goes down perfectly clear, no froth ; until the distilleries begin again you will see no froth on her at all, and you will see also none of that slime and fungus. If you get a small water about the spring time when the pollution is coming in in considerable volume, there is a large amount of fungus forms at the bottom of the river, and then, if you get a spate, I have seen it down below Fochabers Bridge coming down in lumps like sponge as big as my fist ; you have seen it as well. (*Mr. Findlay.*) Well, I am not there at that time of the year. (*Duke of Richmond and Gordon.*) Well, you have. (*Mr. Grant.*) I have. (*Mr. Menzies.*) It is worse in my country than anywhere.

19956. (*Sir William Ramsay.*) Can you get information as to how many distillers in the Spey district treat their refuse?—The total number ; if I remember rightly, there are something like 150 to 180 distilleries scattered through the district. (*Mr. Grant.*) Not on the Spey—about 20. (*Mr. Menzies.*) About 30 or 32. (*Duke of Richmond and Gordon.*) I have got it here. (*Mr. Menzies.*) I forget what there are over Scotland. (*Duke of Richmond and Gordon.*) You see, the Spey district covers a considerable area of country.

19957. Yes, I know?—In the year 1850 there were seven Spey distilleries, only eleven, and they only malted about 2,270 bushels a week. I have not got the particulars beyond 1900, but I do not think there is more ; likely there might be one less probably since 1900, because the distillery trade has had a severe blow.

19958. My impression was that they were numerous?—(*Mr. Findlay.*) I think the map is behind you. (*Duke of Richmond and Gordon.*) In the year 1900 there were 27 distilleries malting 50,850 bushels of malt, as against 2,800 in the year 1860.

19959. They look to be about 25 or 26—something like that. My point was this, how many of these are taking any steps to purify their effluent?—I can get that for you ; I would not like to pledge my word.

19960. We were told how many?—(*Dr. McGowan.*) Seven or eight, I think.

19961. (*Sir William Ramsay.*) Seven or eight? (*Duke of Richmond and Gordon.*) The majority of them are doing something, but the majority of them are doing so little that it is no good ; a good many of them have not faced the seriousness of the position yet.

19962. We have been shown various methods, some of which appear to be more successful than others. But my point was this : Have we only been shown those that were attempting to purify their pot-ale, and are there are a great many there which have not been doing so?—(*Mr. Grant.*) At Rothes they have not done anything ; they have done nothing at all. (*Mr. Menzies.*) No ; but they are going to do the best of all ; they are going to put up the best. (*Duke of Richmond and Gordon.*) It is not for us to say. (*Mr. Menzies.*) No, it has nothing to do with us. (*Mr. Findlay.*) The chief thing they do with the pot-ale is to spread it out over fields, and as long as farmers are willing to take it, and a small distillery has a considerable extent of arable land round about, there is no difficulty.

19963. Quite so ; but is there any difficulty in distillers getting land near their distilleries to put up plant for artificial filtration?—(*Duke of Richmond and Gordon.*) Oh, not if they pay for it.

19964. It is quite possible?—The land could be got. I do not think they could get it at purely agricultural value ; I do not think they would expect that.

19965. Because it is not agricultural land, but is valuable as building property?—Because it is for use for a purpose which will not really benefit the property ; it is not like feuing plots to improve a district. (*Mr. Findlay.*) If it reverts to the landlords, it is no use, as it is covered with concrete tanks or beds with sludge in them, therefore you cannot expect them to part with it at agricultural value.

19966. Quite so?—It would be useless for agricultural purposes for all time to come.

19967. But if the process of sprinkling it over the land were adopted?—(*Mr. Grant.*) I can speak with a certain amount of knowledge on that point, because in this case against the Daluaine Company, the Daluaine Company I understand have a private arrangement with my tenant, who is also one of the managing directors of the Daluaine Company, and they are the joint tenants of the farm, and they applied for help to me to put the burnt ale on to the farm of Daluaine. Well, if you put burnt ale on to land, if any of you gentlemen have seen the result, you will find that it creates such tremendous crops that they threaten to be too luxuriant and rot in wet weather Also if you put on too much you can actually burn up the pasture. Now, it was a difficult point really, but in order to keep myself perfectly justified in continuing this action against the Daluaine Company, though it was very much against my wish, my private inclination, to give land as it creates an offensive smell near my own residence, being an enormous quantity I said I would agree on certain conditions, provided that this was not taken into court, and so I asked them if they would agree to any man of skill I put on. As far as I understand, I really did not go into the actual details very much myself. My agents proposed a certain gentleman, and the Daluaine Company would not have him. They then proposed Mr. Walker ; Port Lethen I think he comes from ; I know him very well ; one of the best known agriculturists in Scotland. I said I would expect him, and he should regulate the quantity, visit the farm, and find out how much of this burnt ale could be put on the land. When he came he said it was all in the nature of an experiment ; it had never been done ; he was not sure how it would affect the rotation of crops. This farm had been laid out by them chiefly for grass, and they have sprinkled on as much of this burnt ale in such a manner as Mr. Walker directs and they have put an extra stock of sheep to feed it off. Mr Walker informed me it is only a temporary measure. It is not right for me, with the case before the House of Lords, to go into any further points about this action, but I think at the same time I would point out that an expert, an independent arbiter, meeting me going over the land with one of the company directors, and the solicitor assured me that the continuation of burnt ale on land could not go on for ever, and also that even if it was put on if it was not to do damage to land it would have to be very carefully watched and very carefully regulated.

19968. I suppose most of the distillers hold from you, do they not? I mean they lease your property, is not that so ; or do they own it themselves?—(*Mr. Findlay.*) The majority of them are feus, the Scottish system of tenure.

19969. Of course ; I know, but it is from you?—Well, there are various proprietors. (*Mr. Grant*) There are various proprietors. (*Mr. Menzies.*) None from me. I was the only one that would not have one, except his Grace.

19970. It is a lease for a number of years?—(*Mr. Findlay.*) A perpetual lease. (*Mr. Menzies.*) They offered me any price I liked to ask ; I would not have them. (*Duke of Richmond and Gordon.*) Upon that point, certainly one of the largest distilleries in Scotland, one of them which gives the name of Glenlivet whiskey, is on my property ; it is far away up, and there is a large amount of land at the disposal of this distillery, and a certain amount of pollution would get through to the river, but not much. And then there is another distillery on my property at Dufftown, that of Dr. Cowie, the gentleman you saw here at the last meeting. But those are feus which my father before me, and I in succession to him, have succeeded to, but nothing would have induced my father to have given off land for a distillery—not from any temperance sentiments, but for the protection of his property.

19971. (*Chairman.*) I think you said, did you not, that the number of distilleries has increased considerably in the last ten years?—Yes.

19972. So that they, at any rate—those new distilleries—have been allowed by somebody to come and settle there?—Those at Dufftown are on the Duke of Fife's ground. I think I can explain that to some extent : the Duke of Fife owned a considerable amount of property in Dufftown and neighbourhood and some of the distilleries at Dufftown ; he sold the greater part of his property, and some of the land which he sold bordering on the Fiddoch was bought for distillery purposes ; whether he was aware of it at the time or not I do not know. He is a non-resident, so it would not concern him, perhaps. (*Mr. Grant.*) I have new distilleries on my property, and I put in these feu charters extremely stringent conditions where I could. The

question actually came to me to be whether I should accept these feus or not, and I, naturally thinking the law of the land decidedly meant and means that a man cannot deliberately set up an industry to destroy and spoil his neighbour, thought perhaps the common law as it now stands would be good enough, that is to say, water must pass in its original state and quantity from one proprietor to another. However, in order to strengthen my position, I have got new charters for the new distilleries on my estate; others I succeeded to, with very stringent clauses indeed. One condition is that they are bound to effectively purify pot-ale, and if they do not, I may in some cases forfeit their feus. I am speaking generally. Another condition in the charter is that if any measures provided by the distillers for the prevention of pollution are not effective I am entitled to have these pulled down and others adopted, the object being that six or seven years ago, when these charters were taken out, I was not going to commit myself as to the proper measures to adopt to prevent pollution, and I do not intend to commit myself now. I tell the distillers either that they are polluting the Spey or the air or that they are not, and if they are, to rectify it; and that is how the matter stands. One distillery I have got now—I am only speaking offhand; I have not got the copies of the feu charters with me, but I will give you the general terms of them—in this particular feu charter about a distillery on the Spey, and I made sure before I came here. I feued it to a man called Thompson; I put a tremendously stringent clause in, but he evidently did not like it, for he never worked for more than a few weeks; he never worked his six years. These conditions are considered somewhat hard, but I may say, without prejudice, that I certainly will not alter them, because if I do I should do not only myself an injury, but my neighbouring proprietors. Those conditions were put in not only to safeguard myself, but my neighbouring co-proprietors, and if the distillers choose to accept a charter with conditions in it they must stand by the consequences.

19973. But do you say that if they pollute at all they must give up distilling?—Pollution according to the common law—that is a thing I speak very strongly on, because I consider it would be a very great hardship, if not an injustice, that the law of Scotland should be altered to suit the convenience of distillers.

19974. I was only wanting to know what you would call a pollution? A thing that has been water and has been used for something else cannot actually become water again; it may become innocuous, but it cannot become water?—A large amount of this water which is used in distilleries is used for driving power; I mean, for instance, they would have a wheel probably worked by a burn to work the electric light of the place; well, the sort of stuff I mean is the burnt ale, and that, I understand, is possible to be treated. I am not here to commit myself as to whether it can be or not. I really do not know; I can tell you if I am satisfied with it, and I think that is as much as is to be expected.

19975. (*Sir William Ramsay.*) Is there any difficulty about the pollution of the air? Do the processes that some of the distillers resort to to get rid of their pot ale by burning or distilling it make a smell in the neighbourhood?—The Tamdhu Distillery Company erected on my estate a plant—I am speaking entirely without prejudice—a plant to deal with burnt ale. I understand it is consolidated by evaporation. It is a very large plant, and I believe it is very expensive to work, and from the deposit that is left they get the deposit and put it on a sort of tray, and then the residue is mixed with the tail race water. They then reduce the stuff that is left into a cake or powder, which they intend to use as a manure. In this process there was, and there is, a very strong smell of burning, which I myself have felt a good many miles from the place, and I wrote to the company some time ago, and said it simply could not go on, and I pointed out to Mr. Willis, who was up visiting the Tamdhu Distillery a short time ago, the farm where the farmer frequently complained to me of the smell, especially in hot weather, and the company admit practically there is a smell, because they are going to endeavour to remedy it this year.

19976. And if there were some process discovered, or if one of the processes which is at present used, were pronounced by competent authorities chemically and bacteriologically to purify the pot ale to such an extent that it practically is water, would you, as proprietors, be willing to give the distillers in the neighbourhood facilities to acquire land for putting up such a building to make it possible for them to do their best to remedy the evil; supposing it was decided, would it be possible to meet them? They complain, I understand, that they have not sufficient land; that difficulties are thrown in their way; if you recognised that they were doing their very best, and succeeded, I presume you would be willing to meet them on the ground that there would be a considerable advantage to you in their holding property of yours and paying a rent?—(*Mr. Findlay.*) I am not aware that any land has ever been refused to distilleries for such purpose, except under circumstances where it has been asked with the view of staying proceedings. For example, if a distiller is polluting, and you want to get a decree declarator that such a state of affairs is existing, they forthwith apply for land, and they want to take time by erecting remedial works, and to get the thing hung up in that way.

19977. I see?—I think any case of land being refused has been simply because it has been a step in the process of negotiation. (*Duke of Richmond and Gordon.*) Procrastination. (*Mr. Findlay.*) Procrastination. I do do not think there is any case of land ever refused where there was evidence that it was wanted for *bonâ-fide* purifying purposes. (*Mr. Menzies.*) No, I am sure there never has been.

19978. But has it been offered at such a high price that it was tantamount to a refusal?—(*Mr. Findlay.*) Not that I am aware of. (*Duke of Richmond and Gordon.*) Well, of course, I cannot speak to a certainty upon this matter for all the other proprietors, but in no case, as far as I am aware, has the price been prohibitive; it may have been large, but I draw a very broad distinction between a large price and a prohibitive one. (*Mr. Grant.*) I have never heard of a distiller commenting on the price of land with me as regards works; they have never come to me and said the rent is prohibitive. I have had a case where the man said the conditions of my feu for the proposed remedial works were prohibitive, but not the price, and I think that was significant.

19979. (*Chairman.*) Have you ever been asked for land for purification purposes?—Yes.

19980. And you have granted it?—No. I have never been asked for land to erect buildings on outside his distillery works, but I have certainly given facilities, as far as are in my power, for the burnt ale to be dealt with—tanks to be put up, so that the farmers might cart it away.

19981. (*Mr. Stafford.*) Do the riparian owners wish to encourage or discourage the industry?—(*Mr. Menzies.*) We wish it was in any other valley except the Spey. (*Duke of Richmond and Gordon.*) I have no personal feeling about it at all.

19982. But do they as a rule wish to grant land or not—the proprietors?—(*Mr. Menzies.*) I will not give any land.

19983. For the purposes of the distilleries?—For new distilleries. (*Duke of Richmond and Gordon.*) As I said just now, nothing would induce my father to do it. (*Mr. Menzies.*) They have asked many times, and have always been refused; I will not have a distillery on my property; that is a different thing. (*Mr. Grant.*) Personally, as long as they do not pollute my property at all, I have not got any personal feeling against them at all. (*Mr. Menzies.*) It is several years now since there was any idea of putting up a new distillery, because the crisis in the trade has been so bad we have had no applications for years.

19984. (*Major-General Carey.*) What proportion of the distilleries are doing nothing at all in the way of remedial work?—(*Duke of Richmond and Gordon.*) Well, I could not tell you off-hand, but I could get you the last report from Messrs. Brodie, our lawyers, if you wish to have it.

19985. The Commission, when visiting the Spey Valley, examined a number of works in which, at all events, attempts were made to produce a satisfactory effluent, some of them varying in success, but there were *bonâ fide* attempts made by tanks and filters?—Quite so.

19986. They were apparently doing their very best then, and they are anxious to get further advice if they can from the Commission?—And possibly you saw a comparatively innocuous effluent.

The Duke of Richmond and Gordon, Mr. John R. Findlay, Mr. W. S. Menzies, and Mr. J. H. W. Grant.
10 May, 1904.

19987. Well, we saw a distinct difference between the treated effluent, and when it was turned into the river without being treated—they turned it in to show the difference—the river was suddenly covered with the frothy matter?—Excuse my saying so; you do not know whether that distillery was malting to the full extent of its capability; you do not know how much of the effluent you saw was a fair sample of the amount that they would be putting in if you were not there?

19988. We took it simply that they were treating all the refuse?—On that I should like to make this remark: the distillers in some cases have tried to hoodwink us by putting the refuse in at night; they run off their tanks; we have found them doing that, and if they will do that to hoodwink us I should not be surprised that they might have had a try at you too. I do not say they have been successful, but I think they might have made the experiment.

19989. (*Chairman.*) I think your Grace said, in case you have not any more remarks to make, that one or two of the other gentlemen had something to say?—I have several more points I should like to put before you before I have done, and then the other gentlemen will have something to say. If you do not want to ask me any more questions on the general point I should like to make some remarks on the statement Dr. Cowie put before you when he was last here.

19990. Certainly?—He deals with the number of distilleries and so forth. The first remark of his which I take exception to—I will not say take exception to—to which I wish to draw your attention is this. He says:—"I must say that perhaps at one time the distillers, like other manufacturers, when this problem confronted them were a little slow to move till they saw how things would go, but I have to impress upon the Commission that I am certain every distiller is now anxious to find some way out of this trouble and to meet the complaints that have been made against them by the proprietors." There I have from Dr. Cowie's own lips the complaint which I mentioned some little while back that our appeals have had so little effect upon them that it is not until they find the law is against them that they really face the difficulty. We have been going on for some years spending money which, if they had taken the question up with vigour in the first instance we should have been saved, or, at any rate, a considerable portion of what we have spent we should have been saved. And then he makes one suggestion which I may say we are all dead opposed to, and that is, any idea of partial purification or the establishment of a central authority. In the case of partial purification, what guarantee have we that partial purification will continue? From our experience of the distillers up till now what guarantee shall be get that the partial purification which they suggest will be continued? I see in one place they talk about purifying up to 90 per cent. Well, I should have thought—I am not an expert in those matters—if you could purify up to 90 per cent. you could purify up to 100. The difference does not appear to me to be a very great one. But supposing you purify up to 90 per cent., what is the ultimate result? The result is the same, to use a homely simile, as filling a bath from a tap or a teacup; it is only longer, the time is only more extended during which the river will become in the same foul condition that it is now; if you have only partial purification it means that a certain amount of pollution is going in; it depends entirely upon the amount of pollution going into the river, how long or how short the time it takes the river to get into the condition which we are now complaining of. Do you see my point?

19991. I do not know that we should quite agree.—That I cannot help.

19992. (*Colonel Harding.*) I suppose the Duke's point is this: that if an effluent is purified to 90 per cent., and if in the course of time, owing to the expansion of distilleries, the volume of effluent is increased ten times, that the sum of impurities would be as great?—Well, to my mind it is only a question of time when you arrive at the same result as you have now. Given a certain quantity of stuff to go into a certain receptacle, whether it goes in in a large quantity or in a small one, it goes in in a certain condition, and it is a question of time how long it takes for that amount to fill a certain receptacle. Do I make myself clear?

19993. (*Chairman.*) Oh, quite so; but I think it possible that we may think the river would do a certain amount of purification itself, and it might be able to purify 10 per cent. quite easily without any damage to the river; but those are matters for the Commission?—Those are matters for the Commission to settle, but I just put them forward for the proprietors.

19994. Might I just ask you this: supposing purification was sufficient to make the water quite uninjurious to fish, is that all you want; I mean, it is not a question of health to human beings; it is a pure question of the fish that you are interested in?—Well, no; it goes further than that. Mind you, a large number of the proprietors who have land on the borders of the Fiddich—for instance, there are some cases in the Fiddich now in which it would mean injury to put your cattle on to drink it.

19995. The cattle drinking it, you mean?—Yes.

19996. Are there cases of cattle suffering from the polluted water?—I will not say. (*Mr. Grant.*) I think, speaking only from memory, that when the Glenfarclas Distillery was working at full power and putting the burnt ale straight down the Daluaine Burn, the farmers did not like to put their cattle to drink there. (*Duke of Richmond and Gordon.*) The point we want very strongly to put before the Commission is this, that our right is to have full pure water. We have been spending a considerable sum of money trying to get it, or rather, to preserve it, and our patience has been strained almost to breaking point now by the distillers. They appear to be, from Dr. Cowie's statement, very frightened of the Court of Session, and they suggest the establishment of some central authority to decide on pollution. Well, that is a point on which we are very strong. The Court of Session is the law court in Edinburgh, which is there for preserving our rights; we do not want any other body, any new body, or any other body set up and established for the purpose of dealing with this; the Court of Session is good enough for us, and probably the distillers are aware now that the Court of Session has decided against them, that the law of the land is in our favour, and I can quite understand that for that reason they might suggest setting up some other authority which they think might possibly take a different view. From what Dr. Cowie says, more than once, his dislike to the Court of Session is very evident. "Do keep us out of the Court of Session." "Can you not get the proprietors to arrive at some arrangement with us, and avoid the Court of Session?" They all appear to be frightened of the Court of Session, which I consider a very healthy sign. And I do not think, with regard to the question of a central authority, that they need have this fear of the Court of Session which appears to be coming before them, because they have been very fairly treated in the Macallan case. Lord Kyllachy was the judge, and in that and every other case that we had had up no onerous conditions had been imposed upon the distillers, but rather they had been granted time. In the case of the interdict that we got in this particular case, which was decided by Lord Kyllachy, they got a year. (*Mr. Findlay.*) It was suspended during the pleasure of the Court. (*Duke of Richmond and Gordon.*) All those interdicts have been suspended until the distillers have had a considerable amount of time to endeavour to make some arrangements. Well, then, I see Dr. Cowie in one place says—I think it is Mr. Grant, it was not Dr. Cowie, there. He says Dr. Cowie has said they have no wish to adulterate the rivers. I daresay they have not, but our complaint is that they do.

19997. May I ask you when the first case that you took action against them was?—(*Mr. Findlay.*) The Kemp case began in 1895—at least, the correspondence. (*Duke of Richmond and Gordon.*) It was concluded in 1898. The date of the reclaiming note was October, 1898.

19998. Then the decision had been given in your favour in October, 1898?—It went on for two years, but that was the date of it.

19999. That was the first case?—That was the first case.

20000. But you still find it the exception rather than the rule that any steps are taken to purify?—I wish you could see it any Friday or Saturday afternoon. With regard to that, you say it is the exception to have taken any steps.

20001. Yes?—I wish to be perfectly fair about it; I will not quite go the length of saying it is the exception to have taken any steps which are likely to be productive of any good. Some of these distilleries, I think, as I said just now, were malting a large quantity of barley. They had put up retaining tanks; they must have known it was ridiculous—filter-beds close to the river. Some of the Commissioners are probably aware that some of the refuse has formed into a sort of thick slimy condition, which, instead of draining from gravel beds, as other forms of sewage pollution will, plugs up everything immediately the place gets full, and it just runs over into the river. That is all. Our complaint is that they have not taken it up earnestly. The position we wish to assert is that we want nothing more than the law gives us now, and that we are entirely opposed to any new authority being set up to deal with the question. Those were the three points upon which we are strongest. There is a letter from Sir Charles Logan, Lady Seafield's agent, who is unable to come here; and perhaps it would be as well if I read to the Commission a passage from his letter. Sir Charles Logan wrote to me, and I wrote back my views to him, and he says:—"What you propose to state to the Commissioners appears to me quite the right way of laying before them the views of the fishing proprietors." And he says:—"That it should be brought clearly out that the distillers have no right or reason for posing as martyrs who have been hardly treated, but that for years past efforts have been made to induce them to adopt remedial measures—which they have obstinately resisted—and it is only now, when they find that the law is against them, that they are seriously and honestly facing the difficulties and realising that they must take some steps to remedy the evil or must take the consequences." Well, that is from Sir Charles Logan's letter, who is Lady Seafield's representative, and she is, I daresay many of the Commissioners are aware, one of the chief proprietors in Scotland. She owns a large property on the Spey. If there are any other points upon which the Commission would like any other information, I should be happy to give it.

20002. (*Colonel Harding.*) I should like to ask one or two questions. You referred to the wonderful expansion of this industry in the district of the Spey?—Yes.

20003. Can you tell us what is the cause of that industry being there localised and so largely increased?—Well, conditions, of course, affect it; you know how industries do increase. Now, for instance, if you look at the town of Kirkcaldy, it is wholly given up to the manufacture of oil-cloth and linoleum. Now, there is nothing special about the town of Kirkcaldy which is favourable to the manufacture of linoleum, but I think you will find that, given water is good for making whisky, the distillers will always come down and get that water, because, mind you, it is not every water that will make whisky.

20004. Then it may be due largely or partly to the special quality of the water in that district?—Quite so; there is one distillery which possibly some of you may have seen on the Highland line up near Dalwhinnie. It is not working; they spent a lot of money building it, and I have asked why nothing was doing there, and I was told that the reason why it was shut down was that they had found that the water was unsuitable for making whisky, and I think that in all probability the reason for the distilleries having congregated on the Spey side is that the water in that part of the country is more suitable for making whisky than in other places. And Mr. Findlay has reminded me there is a trade reason for it. Glenlivet was what you might almost call the pioneer of distilleries, and Glenlivet whisky had a very important name in the market. It was a guarantee of goodness, and a large number of these distilleries having come into that district, now also attach to the name of their own distillery the word "Glenlivet." It enhances the value of the product that they are making to be enabled to get the mantle of Glenlivet thrown over them. (*Mr. Menzies.*) It is absolutely untrue; there is no Livet water in any of them.

20005. May I ask your Grace whether any of the distilleries have leased lands from yourself?—(*Duke of Richmond and Gordon.*) Leased?

20006. Yes?—There is the Glenlivet one which I succeeded to, which my father succeeded to, and which his father before him succeeded to; that was a feu. There is another one, a very old one, on the Fiddich, which we succeeded to in the same way, and I am not aware that there is any other.

20007. Then, so far as your estate is concerned, you are able to prevent the extension of distilleries by refusing to lease land or to sell it for that purpose?—Well, no; because the original feu provides a certain amount of land, and I cannot control the amount of building which the holder of the feu chooses to put up.

20008. But you can prevent the creation of new feus?—On, yes; but where I feued, say, take, for example, ten acres, a man, we will say ten or twelve years ago, only had one acre of building on that; I cannot control the amount of building he puts up on the remaining nine acres. Do you know what a feu charter is—the difference between it and a lease?

20009. I am afraid I have only a vague idea?—A feu charter is a making away with your property for all eternity for a small sum.

20010. It is equivalent to a lease?—It is interminable.

20011. It is equivalent to a 999 years' lease?—Yes, or double that. (*Mr. Menzies.*) That is it.

20012. Then, I suppose the Commission may take it that the concentration of distilleries in Glen Spey cannot have been due to the facilities with which these feus are obtainable, if we may judge at least from the exceedingly stringent conditions which Mr. Grant has referred to?—(*Mr. Grant.*) I can also offer you another reason; there were many, many more distilleries 50 years ago on the Livet and the Spey than 20 years ago, because, along with many farms, there were small distilleries attached all over the country, and the reason of the origin and the growth of a lot of the present large distilleries was simply because by the amalgamation of one interest with another, one disappeared and another started on; and if Sir George Macpherson Grant were here to-day, he would tell you that these small places really used to be let along with the farms. It was not a distillery and a farm; it was a farm and a distillery, and in many cases, what was formerly a very small concern, has now grown up into one of these big places.

20013. Do not all these distilleries represent a very large capital value, and may we not take it that these distilleries have a value locally in promoting the agriculture of the district?—(*Duke of Richmond and Gordon.*) Oh, no. Certainly not a large one.

20014. Do they exercise no influence whatever in the raising of certain crops?—(*Duke of Richmond and Gordon.*) Barley is the only crop which is required for them.

20015. Would the complete removal of the distilleries affect the agriculture of the district at all?—I do not think it would. Mind you, the distillers will only buy good barley. At the present moment Morayshire is a fine agricultural country, and it grows very fine barley, but a distiller will not think of buying a second-class barley in Morayshire for the sake of benefiting the country; if he sees he can get a better barley abroad cheaper, you do not think he is philanthropic enough to buy Morayshire barley.

20016. Then it is not the quality of the local barley which makes that district an attraction to the distillers?—No; I think it is more the water than the grain.

20017. Then there is nothing in the suggestion that there is a quality in the grain itself which causes the localising of the distilleries?—Oh, no; there is no guarantee that your whisky is made of home-grown barley. Gilbey does in one or two that he has acquired.

20018. I see in the statement Dr. Cowie made to us, and which you had before you, that he says that "this industry employs a large number of workmen, both directly and indirectly. It affords an outlet for barley and other agricultural products of the neighbourhood where the distilleries are situated, and also gives cheap cattle food," which, he goes on to say, at times is of special value. Your Grace does not seem to think that there is anything in that statement?—It is so cheap; they make a great deal more than all the cattle in Morayshire can eat.

20019. But has it not a value for cattle food?—It has a small value, but nothing excessive. If it were really a valuable cattle food, they would be able to dispose of it. (*Mr. Grant.*) It is the draff they dispose of for cattle. (*Mr. Menzies.*) What they call the draff. (*Duke of Richmond and Gordon.*) It is one of the sediments; I forget how he arrived at it. (*Mr. Findlay.*) It is what is left in the mash-tub.

20020. But the burnt ale is commonly used for cattle?—(*Mr. Grant.*) Certainly.

The Duke of Richmond and Gordon, Mr. John R. Findlay, Mr. W. S. Menzies, and Mr. J. H. W. Grant.

10 May, 1904.

20021. It has a certain value, or it would not be used?—It has a value. (*Mr. Menzies.*) It is infinitesimal. (*Duke of Richmond and Gordon.*) It has a value in one way, but not in another; it has a value to the extent that it is a good food for cattle, but it is of very little value really to the distiller, because he in many cases gives it away. He says to the farmer, "If you like to come and cart this away and give it to your cattle, you shall have it." It is not a marketable product to the distiller.

20022. Then we are to take it that in your Grace's opinion, although burnt ale is used locally for cattle food, that great industry is of no local value?—Oh, no. (*Mr. Menzies.*) If I did not have a bit of draff on my home farm, it would not make one bit of difference. (*Duke of Richmond and Gordon.*) It does not make an appreciable difference; it is a convenience. (*Mr. Menzies.*) It would cost you very little more to get something else. (*Mr. Grant.*) It is the burnt ale I was referring to.

20023. My object is rather to point out that it would be to the interests of the locality that the local landowners should assist distillers now that they are evidently showing a desire which, although not at first earnest, now certainly appears to be earnest, to solve the great difficulty which lies before them?—(*Duke of Richmond and Gordon.*) I see what you mean. (*Mr. Grant.*) Are we to suffer all this time? May I ask, are we to allow these men to go on? My own personal experience with the Daluaine case has been extremely unfortunate.

20024. Mr. Grant, would you allow me to finish my questions to the Duke? I will afterwards deal with you. In regard to the condition of the Fiddich, we were told when we visited that district last year that, although its condition some four or five years ago had been obviously bad, and at certain times the stream was covered with very considerable growth of fungus or *leptomitus*, that there had been within recent times considerable improvement in the condition of that stream, and certainly when we visited it there was no evidence of the presence of that fungus, and, though it is unlikely, perhaps, that we should have seen it at its worst, we did not see the froth floating over the surface; but we were told by persons not connected directly with the distillers that there had been a distinct improvement in the condition of the Fiddich, and I should be very much interested to know whether the Duke himself has been able to form any opinion as to whether there has been in consequence of the works which have been carried out at the Mortlach Distillery and others, any improvement at all in the stream?—(*Duke of Richmond and Gordon.*) I think there has been a slight improvement, but with regard to what you say about not seeing any fungus, I should like to point this out, that although you might not have seen any when you were there, was the river big at the time; was there a big volume of water, a spate, or anything?

20025. I am unable to say, having only seen it once, whether there was an unusual condition?—The heavy water will wash the stuff away.

20026. It was about May last year; it did not occur to me that there was any spate on. The important point which was laid before us was that whereas three or four years ago there had been very evident growth of fungus, there had not within the last year or two been any evidence of the fungus; and certainly at the time when we were there, and we inspected the stream rather carefully—we were there some time—we saw no evidence of the presence of fungus then?—Well, fungus will come and go, you see, in this way, that if you get a heavy spate you will wash a great deal of it clean away, but the moment the river drops the least, the moment the flow of water diminishes, and the effluent is being put into the river from a distillery, then your fungus comes on and on again.

20027. But, as one of my colleagues reminds me, it was rather a dry time; probably we saw the river at its worst?—Well, at the end of May very likely there was not much work going on. (*Mr. Menzies.*) The spring floods would have washed every bit of fungus away.

20028. The point I wanted to get at was, whether the work carried out at Dr. Cowie's distillery, where a serious effort had been made to meet the difficulty, and where a very evident improvement has been brought about with the effluent produced, as compared with the very foul matter turned out of the distillery, whether those efforts have led to any improvement in the stream?—(*Duke of Richmond and Gordon.*) I think Dr. Cowie's was a *bonâ-fide* effort, but it failed so absolutely, that only since the 1st January—I have not the exact date by me—we took a sample of the effluent from Dr. Cowie's distillery, and we sent it up to Edinburgh to be analysed.

20029. When was that?—That was since January; I think it was in the month of February.

20030. This year?—This year. We sent it up to Edinburgh to be analysed, and the report of the analyst was that it was the worst form of pollution that we had hitherto submitted to him. I can get the report, and if the Commission would like it I would send it on to you.

20031. But is it suggested that the effluent which was then analysed was worse than any sample of crude matter turned out from the distillery that had been submitted for analysis?—I think it was as bad, if not worse, than any that they had ever had.

20032. Was it really suggested that no improvement had been brought about in the burnt ale by the treatment which was given to it?—Dr. Cowie's first attempt was with bacteria beds. Well, they appeared to promise well, but the bacteria beds got choked, and I think he would tell you himself that he is now satisfied that the bacteria bed is a failure for the purification.

20033. I did not gather from his evidence that that was his opinion. I think he did tell us that bacteria beds alone, he thought, would be somewhat likely to choke, but he has introduced other processes, certain treatment by lime, I believe, and a subsequent treatment after the contact beds by a percolating filter, which, we gathered, were rather promising in their results?—Yes; what I meant was this: I think that the first attempt Dr. Cowie made was with bacteria beds pure and simple. (*Mr. Findlay.*) So I understood.

20034. That did not seem to bring about a satisfactory improvement?—(*Duke of Richmond and Gordon.*) No.

20035. There was improvement, but not sufficient improvement?—No; and they got choked in a very short time.

20036. Since then, we understand Dr. Cowie has been settling the solids as much as possible, and treating with lime, and he now finds a very considerable improvement?—I have not taken a sample from Dr. Cowie's distillery quite recently, but I should like the Commission to read the report I have just referred to.

20037. Then your Grace is quite unable to express an opinion as to whether there has or has not been any improvement in the condition of the Fiddich within, say, the last few years?—I would rather ask you to put that question to Mr. Menzies, whose house is within a mile of where the Fiddich runs into the Spey. (*Mr. Menzies.*) I should only say the Fiddich has never been in a worse condition, owing to the distilleries letting out their tanks, than it has been this spring. Many of my own tenants can prove it. Nothing has been done to improve it, and the Fiddich has never been in a worse condition, or the water down below. That is simply because—not Dr. Cowie, who is the one man in Dufftown who has really done his best, in my opinion, but others have let out their tanks every week.

20038. May I put this to you in another way: Is the condition of the Fiddich below Dr. Cowie's distillery in any way improved by the work that he has carried on?—I see no improvement at all. I do not know his distillery from the others.

20039. The work hitherto carried out by Dr. Cowie is useless?—There has been no improvement in the Fiddich this spring. I have lived there these 30 years, and, as to the salmon spawning, I can only corroborate his Grace in what he has said, that no fish have been able to spawn in the Fiddich for some years since the distilleries became so numerous.

20040. These distilleries' feus must be of considerable value to you?—(*Mr. Grant.*) Yes; well, that, of course, is a private question.

20041. I do not want to press that, but merely to get the general fact that they are of a certain value, that the destruction of that industry on your estate is perhaps not desirable?—I cannot express an opinion as regards the destruction of distilleries, because I hold that, personally, I have always taken an extremely lenient line in dealing with them.

20042. Are the conditions you referred to in all your feu charters?—No, I cannot say that they are in the feu charters that I have got on the distilleries that I succeeded to from my father and my grandfather; I can-

not put in stringent clauses in them, but, mind you, when my father feued the Daluaine Distillery to the Daluaine Company it was a little tiny building attached to the farm, and directly they got that feu, and he died, and I succeeded, they began to build, and they have been building practically ever since. Nobody could conceive, at the time they got that feu, that the distillery would be so largely developed, as they had at first a very small distillery.

20043. The industry has developed?—As his Grace has said, you cannot control building.

20044. I think you said that one of the conditions of the charters was that, not only should the quantity of water which left the stream be put back into the stream, but that it should be the same quality when it was returned to the stream?—I referred to that; I did not know that it was necessary to put that into the charter; I understand that is the law of the land.

20045. Would that, in your view, prevent the evaporation of burnt ale?—I may say, speaking generally, without committing myself, as regards this question, that I have really been rather fortunate, I think, in my own dealings with distilleries on my own property, because though we have got an action against the Daluaine Company, speaking absolutely personally, I must say that the Tamdhu directors, and also the directors of Cardow, have informed me that they have spent considerable sums, but I will not commit myself to say whether this is right or wrong.

20046. You mean that you express no opinion on the question whether the expenditure has been wise or otherwise?—Yes; but I will not deny, because it would be absurd to say, that they have not done anything, these two companies, because they have spent considerable sums of money.

20047. We have been told that they have both spent considerable sums?—I do not doubt it. It does not alter my decision if they pollute the river. Because they have spent considerable sums, they have both made considerable profit, and though they have spent this money, they must keep the law.

20048. What strikes me, as a Commissioner, I may say, is this, that the position that is taken up by yourself and other landowners seems justifiable enough, in view of the complete unwillingness of many of these distillers to do anything for many years, in view of their turning out the most foul effluent into streams, and apparently not recognising any duties to purify their effluent. But at the present moment, when very evident efforts are being made by distillers, and when considerable sums are being expended by them to solve their difficulty, one cannot but feel that a certain amount of patience on the part of the landowners, and a certain amount of assistance on the part of the landowners, might bring about a very great improvement; is it not possible?—I think the only answer I should suggest to you is this, if you are going to be very much more patient with some of them, we will lose our prescriptive rights. (*Mr. Menzies.*) You cannot do that; you cannot lose prescriptive rights. (*Mr. Grant.*) If we go on being tolerant for ever, will it become a right? (*Mr. Menzies.*) The Rivers Pollution Act would stop that.

20049. There is evidently an effort being made to solve the difficulty, and they have appealed to this Commission to investigate the matter, and they have expressed a general readiness to carry out works which may be suggested, and so forth, and there does seem a prospect of this great difficulty being solved, not to the point, possibly, of restoring the water to absolute purity again, but of restoring it to such a point that the stream itself would readily oxidise the remaining impurities, and so therefore you might consider the effluent to be innocuous (*Mr. Findlay.*) Migh I remind you, Colonel Harding, that in 1901 there was a form of agreement submitted to the distilleries by which they got a year's grace, during which no proceedings were taken whatever, to take steps, and the experience of the proprietors of that year was not very encouraging. We have been giving time all along.

20050. I may say that I am Chairman of a Rivers Board in Yorkshire, where we have to deal with countless pollutions, and we earnestly hope that your beautiful Spey stream may not become like one of our streams, but we have there the same difficulty with manufacturers, and we get very many promises and very little performances. But where we do find a manufacturer who is striving with his difficulty we find it policy to assist him in any way we can?—Unfortunately, some of them will not strive. There are one or two who are working hard, but we have got 27 people to deal with, and the question is, what position are we to adopt with regard to, say, the other 20? If you have seven making experiments, are the other 20 to be allowed to continue to pour all their burnt ale into the stream?

The Duke of Richmond and Gordon, Mr. John R. Findlay, Mr. W. S. Menzies, and Mr. J. H. W. Grant.

10 May, 1904.

20051. There is just this difficulty, you see, that this question is at present in a transitional state; it is in the experimental stage, and I daresay the 20 are watching what the few are doing, with the idea of adopting some process pronounced to be successful?—Well, there is no doubt by the persistent pressure that we have brought to bear upon them during the last 15 years the whole 27 are very much more careful. I do not say they are as careful as they should be, but they are very much more careful than they were. (*Mr. Menzies.*) They are very careful to put it in at night. That is all they are careful to do.

20052. The last question with which I will trouble the deputation is this: I should like to ask the view of the Duke of Richmond upon the statement made to this Commission by Mr. Grant—not the Mr. Grant present to-day, but Mr. Grant who said he was at once a distiller and a fisherman, and his experience warranted him in saying that the fishing was at least as good now in that part of the river, where he fished near his distillery, as it was any time before there was a distillery?—(*Duke of Richmond and Gordon.*) What is that particular statement?

20053. In the statement which I think your Grace has had before you?—What number was it?

20054. I will refer you to the particular page. "(Mr. Grant.) I have fished the Spey for 46 years steadily every year, and in my opinion the effluents that are going into the river do not in any way hinder sport—not in the slightest. I have had experience; my father had the fishing below where this Daluaine Distillery is for 21 years; I fished it during his lifetime, and I had it for five years myself immediately below where the Daluaine Distillery effluents were going into the river. I have seen the burnt ale coming into the top pool, and it ran down the side, but in the second pool the water ran to the side, and consequently the whole of that pool the burnt ale was distributed right over it, and I have killed many and many a hundred salmon in that pool when that effluent has been going down.

"Do you suggest to us that pot ale is an excellent thing for improving the condition of the river for fisheries?—I do not say that it is an excellent thing for improving the condition of the river, but it does not hinder sport." Then Sir Michael Foster asked him, "Not only now does it not injure sport, but it has not done so in past years?" and he says, "Certainly not." Well, that merely shows that the statement that the Spey has been very gravely injured by these effluents is not acknowledged by everyone?—When I read this answer of Mr. Grant's, No. 19737, I was amazed that anybody who had ever had a fishing rod in his hand, and had gone down to the banks of the Spey, should have the temerity to make such a statement as that. You must remember that he is a very big distiller, the very biggest distiller on the Spey; he could hardly talk otherwise. (*Mr. Findlay.*) With regard to his statement as to the water immediately below the Daluaine Distillery, Mr. Grant has not fished that water for 20 years. (*Mr. Menzies.*) More than 20 years. (*Mr. Findlay.*) More than 20 years, and the top pool below the Daluaine Distillery has been so filthy, that for many years it was quite impossible to fish it, so Mr. Grant's experience of this particular water is 25 years old.

20055. (*Chairman.*) May I ask you whether, having regard to the fact that some of the distillers are taking action for improvement, you see any reason to hope that they will be able to do it efficiently?—(*Duke of Richmond and Gordon.*) I would not confine the distillers who are taking action to any definite number of seven or less; I think they are all doing something, and they have evidently all the sense to see that something needs to be done, but whether they are all doing enough is another question. Then I understand your Lordship wishes to ask me——

20056. I wanted to know whether you could see any signs of improvement?—Oh, certainly: I think there are indications that the stuff can be satisfactorily dealt with, and may be satisfactorily dealt with. I do not believe all our labour during these last 10 years has

The Duke of Richmond and Gordon, Mr. John R. Findlay, Mr. W. S. Menzies, and Mr. J. H. W. Grant.

10 May, 1904.

been absolutely in vain; I believe they are getting nearer their means of purification.

20057. Because, of course, the analyses that you got of Dr. Cowie's effluent from Edinburgh must have been very discouraging, but I take it that the analyses which our own chemist, Dr. McGowan made, would be of an encouraging character?—(*Dr. McGowan.*) Yes the first was very good indeed, and the second. (*Mr. Findlay.*) Well, I think I may explain, with regard to that, that the analyses to which his Grace referred was before the introduction of this precipitation process. I think since then results have been more satisfactory. (*Dr. McGowan.*) I rather think it was before he put on the circular filter—the continuation filter. (*Colonel Harding.*) That you got a good sample? (*Dr. McGowan.*) It was after that I got them; it was immediately improved after that. That was going in January, so presumably your Grace had the sample before then? (*Duke of Richmond and Gordon.*) I could send the Commission the date. I do not wish to misrepresent anything. If the Commission wish that document I could send it to the Secretary.

20058. (*Colonel Harding.*) The Commission, I think, would be anxious that experiments with bacteria beds should not be discouraged by the impression being carried away that they were quite worthless because the analyses which our own experts have carried out were somewhat encouraging. But there can be no doubt—I think Dr. Cowie himself will agree to it—that the bacteria beds as at first installed, and without antecedent precipitation and lime, were not of great value. There was an improvement, but not sufficient. (*Mr. Findlay.*) Another unfortunate circumstance is this, that the proprietors had no indication of the extent to which the distillers used these things. I mean they may put in a sample and treat it from day to day, and then produce a very fair effluent at the end, but we have no indication that the capacity of the beds is sufficient to deal with the whole of their waste products.

20059. I should like to ask the Duke of Richmond an important question, and it is this, that inasmuch as the Commission is investigating through its own experts very carefully not only the experiments that are being carried out by land treatment and by evaporation, but those which are being carried out by bacterial methods, whether it would not be possible in some way for the riparian owners to stay their hands for a certain period in order to give time for the distillers to find out exactly what is the best way of dealing with these matters. Quite a large number of experiments are being carried out. They are being carried out with every readiness to place them under our supervision; they are being supervised by us; we ourselves shall form an opinion upon them, and report upon them, and in those circumstances is it quite wise or generous to press the distillers until a certain time has been given to find out these results?—(*Duke of Richmond and Gordon.*) I do not think I could give that pledge. (*Mr. Menzies.*) I should have thought nine years was about enough for most people. (*Duke of Richmond and Gordon.*) I have no idea when this Commission is going to report, and assuming that this Commission did report in a direction favourable to us, I am then quite ignorant as to what length of time would elapse before legislation would ensue on the subject. I could not on behalf of the other proprietors give a pledge to take it lying down for another seven years as we have done for the last seven.

20060. (*Chairman.*) Of course, this scientific inquiry is very slow, and I am afraid we should hardly be able to begin this, Dr. Houston, for another year?—(*Dr. Houston.*) I should not think so.

20061. (*Chairman.*) What you have got in hand will take you, roughly speaking, a year?—I think Dr. McGowan will tell you. (*Dr. McGowan.*) I should think fully a year.

20062. But in the meantime the distillers are, at any rate, making some experiments?—Well, Dr. Cowie is the only one with whom I have communicated.

20063. But, at all events, the distillers have expressed their readiness to carry on experiments and to take any advice; in fact, to carry out any experiments that our experience will lead us to suggest to them.

(*Secretary.*) Yes, they have informed the Commission of their willingness to do this; their position rather is that they do not want to be spending money on what may turn out to be useless. For instance, that evaporating process, which has been referred to as "the best of all," is very costly, and there are some reasons for thinking that it is not as satisfactory as it has been supposed to be. (*Duke of Richmond and Gordon.*) Well, I think the Commission will see that we have not been unreasonable in the past, and I think they might trust us not to be unreasonable in the future, but I must decline to give any guarantee as to the particular course of action we may find it necessary to take.

20064. (*Chairman.*) I should not like to ask you to pledge yourself?—That was rather what Col. Harding asked.

20065. (*Colonel Harding.*) I scarcely asked for a guarantee or a pledge, or even for a promise; all that I wanted to ascertain was whether there would be a willingness on the part of the landlords in view of the earnestness with which the matter is now being taken up by distillers, and in view of the fact that we are watching those experiments, to hold their hands, to allow time?—(*Mr. Menzies.*) We do not allow that willingness; that is the only thing.

20066. We quite admit the position the landowners take up is justified by the refusal of these distillers for many years to do anything, and justified by their statement in some cases that they had a perfect right to pollute the stream, a statement with which, as chairman of the Rivers Board, I am quite familiar?—Which most of them still think.

20067. But the position of affairs has very considerably changed within the last few months?—Meanwhile, if we give them another four years, all leases to fall in will be down half in rent.

20068. Some of our experts who were over there recently do not appear to have been struck with any foul condition of the streams when they were there. I see that they say—I suppose this is the Fiddich—"We inspected the river for several hundred yards immediately below the town, and also a long reach about a mile below the town, and found it apparently free from any serious pollution." And in another paragraph they say:—"The river and streams into which the effluents flow seemed to be clean and in good condition"?—That was not a fair time of the year. (*Duke of Richmond and Gordon.*) But might I ask this question: were those samples of the river taken on days when the effluent was coming from the distillery?

20069. This is a general observation?—If you were to go to-day below a certain distillery you might find nothing, because the waste products from the whisky making are going into the tank, but to-morrow he lets his tank go, and you will find a totally different state of things.

20070. One quite appreciates, of course, the feeling of large landowners that this condition of things must not be allowed to get worse?—I do not want to suggest that the distillers are always trying to cheat us; I do not go so far as that; but unless you are aware of the conditions of work going on at a distillery when a sample is taken from a river below that distillery, it is valueless, because to-day it is good; to-morrow it is bad. (*Mr. Menzies.*) You must live on the banks to know anything about it.

SEVENTIETH DAY.

Thursday, 8th December, 1904.

PRESENT:

Colonel T. W. Harding, J.P., D.L., in the Chair. | Major-General Constantine Phipps Carey, C.B., R.E.
Mr. W. H. Power, C.B., F.R.S. | Mr. T. J. Stafford, F.R.C.S.I.

Mr. F. J. Willis, *Secretary*.

ALSO PRESENT:

Dr. A. C. Houston. | Dr. George McGowan.

Mr. Herbert Hughes, C.M.G., called in; and Examined

20071. (*Chairman.*) Mr. Herbert Hughes, you are, and have been for many years, the Clerk of the Mill-owners' Association of the River Don?—Yes.

20072. Would you be good enough to explain to us what part of the River Don that covers?—The whole of it to the boundary of Sheffield.

20073. That does not include Rotherham?—No, it does not include Rotherham.

20074. We have heard of the Don as a very polluted stream, but that description would be applicable rather below than above Sheffield?—Yes.

20075. Above Sheffield, I take it, the Don is fairly pure, is it not?—Yes, reasonably pure.

20076. (*Mr. Power.*) Do they catch fish in the Don, in that portion of the river?—No, I doubt it; there may be fish in it, of course; but it is not a river that you would resort to for that purpose.

20077. (*Chairman.*) But there are a few mills in the Don above Sheffield?—There are a good many mills on the Don above Sheffield, and on its tributaries.

20078. How many mills—six, eight, ten?—Oh, more.

20079. How soon do manufactories appear on the Don?—Well, the highest up is at Thurlestone.

20080. Is that much above Sheffield?—About 15 miles above Sheffield.

20081. Then most of your manufactories, I assume, use their mill dams for the purpose of power producing?—Only power.

20082. They are not manufactories turning out trade effluents at all?—With one exception on the Don; that is a paper mill, and there are one or two wire works which may possibly turn some acid into the stream.

20083. Which is the first dam you have on the stream?—Bullhouse Mill, Thurlestone.

20084. Is that the one which formed the subject of recent legal proceedings?—Yes.

20085. Well, the questions that I would put to you, Mr. Hughes, would be on two points, namely, first, as to whether dam sludging did cause inconvenience or nuisance; and, secondly, as to whether the modification of the law, with a view to preventing dam sludging, would seriously affect the manufactories of your Association; and whether there is not some alternative to the present methods of sludging which would be less objectionable than the present ones are alleged to be. Now, first of all, on the question of pollution, I may take it, I suppose, that it depends on the character of the stream itself?—Everything.

20086. Whether the stream is a polluted stream or is a stream of fairly fresh water?—Everything depends upon it.

20087. Therefore the evils of dam sludging would be necessarily very much greater in a polluted than in a pure stream?—Yes; a dam can only receive what comes to it down a stream, and the consequence is that if preventable pollution is permitted—and especially riparian pollution—some of the results of that will come into the mill dam; if, on the other hand, you could imagine a stream in which there were absolutely no riparian pollution, then it follows as the night the day that there could be no polluting matter from the dams.

20088. Well, not quite necessarily, because the upholding of the suspended matter found in a fairly pure stream would involve some putrefaction, though possibly not anything like so important putrefaction as would take place in a polluted stream?—Yes; in precisely the same way as in the natural run of a stream you get the sludging process carried out by the river, which undoubtedly might produce, and does produce, some amount of putrefaction. Of course, coming down the stream you get alluvial detritus, and you also get a certain amount of vegetable matter. Now, what does a stream do for itself, a stream like the Don, which is the only one as to which I am giving evidence to you to-day? What happens?—Upon the saddle back, the Pennine Range, as we call it, the division between the East and the West, roughly speaking, you get an enormous rainfall. Well, there comes a storm; down comes the stream heavily charged with alluvial detritus for the most part, but also, of course, with vegetable detritus. Well, what happens is this: As soon as that flood has spent its force there is a check, either from a turn in the river or from a variation in level, of all that mass of stuff, and there it remains until the next flood comes; and if the last flood was in February, and the next one is, as often happens, in the following autumn, the same putrefaction would go on there in the reaches of the river as goes on in the dams. I have no right to ask questions, only to give evidence; but what I want to ask is this: How can this sludging of the dam be reasonably objected to, if there has never been heard of a case of illness even, let alone danger to life from the effects of sludging dams? You know we have had to go—if I may use a homely expression—through the small sieve with regard to this question of sludging in recent years. You know the Rivers Board—as to whom, on ground of courtesy, we are the best of friends—told us that they intended to put in force their powers under their Act—I dare say you have had that brought before you, the 57 and 58 Victoria. They intended to stop dam sludging, because they said that even having regard to the saving clause which makes it no offence "to put, or permit to be carried, into any stream any sand or gravel or natural deposit——"

20089. Natural?—"Natural deposit which shall have flowed from or been deposited by the current of any such river or stream: provided that the sand or gravel or other natural deposit so put back or carried as aforesaid do not interfere with the due flow of or pollute the waters of such river or stream." Dam sludging was an offence. They said: "Under that we were going to try the question of dam sludging, because we are content that it both interferes with the flow of and pollutes the river." Well, that was, so to speak, if somewhat hostile, nevertheless done in a friendly way; and we agreed that we would take this Bullhouse dam and we would sludge it in front of everybody interested.

20090. The Bullhouse dam being the first dam on the stream?—The first on the stream, and we would try this put by the evidence of what they had seen during the process of sludging; and, accordingly, on a given day, notice having been given, we proceeded to sludge our dam, which had not been sludged for 12 months before. It was done in the ordinary way; I do not know whether you have had any evidence as to how it is done; you

Mr. Herbert Hughes. C.M.G.
8 Dec. 1904

Mr. Herbert Hughes, C.M.G.

8 Dec. 1904.

simply let the water run through the dam and you loose the masses of sand and detritus, and it goes on down the river in the ordinary way. Well, now, we had that dam sludging, and we had many eminent gentlemen there who both examined the process, took samples of the effluent, and generally instructed themselves as to what happened during the process of sludging. Following that, which we expected, of course, was a summons before the West Riding County Bench, Barnsley, for interfering with the flow of and polluting the stream. Of course, the form of the thing was for putting solid matter in the stream, and we, of course, urged that our exemption covered what we did. They said: "No; you both interfere with the flow of, and you pollute, the stream." Well, evidence was taken there, and the magistrates dismissed the case. Evidence was taken again before the County Bench in the Quarter Sessions. There were a great many magistrates present, but I do not know that that mattered very much. What does matter very much is that the West Riding Rivers Board used—perfectly legitimately and fairly, but nevertheless did use—every means in their power to prove that this sludging would interfere with the flow of, and pollute, the river, the bulk of the evidence being given on pollution. I can tell you what a strong case was attempted to be made against us by telling you that they fetched Sir Frederick Bramwell down to give evidence on the subject, and he gave lengthy evidence, the result being that the case was dismissed again. Then under this special Act of theirs, the defendant being a public body, could appeal to the Divisional Court. They did so appeal, and the case was argued before Mr. Justice Wills and Mr. Justice Kennedy. At the end of this lengthened argument, unfortunately, one of these little judicial difficulties arose which do arise in these cases. The two learned Judges had some doubt as to whether they were able to deal with the facts; whether the appeal to them was not one purely of law. In that case, of course, they would have had to dismiss the case again, because the facts had been ascertained and adjudicated upon by the Courts of Quarter and Petty Sessions. When they had come to the conclusion that they could hear an appeal on the question of fact, it turned out that owing to Assize work and illness the Court could not be reconstituted, so we had to begin *de novo*, and we argued the whole case out on law and on fact, and the case on behalf of the Rivers Board was argued by no less able a person than Mr. Tindall Atkinson, who, you may depend upon it, made the most of his case, as he always does. The Court dismissed it again on the ground, which is the important one, if you will allow me to say so, from your point of view, that this sludging of the dam did not interfere with the flow of and did not pollute the river.

20091. Then that was the conclusion, Mr. Hughes, in connection with the sludging of the dam, which was the first on the pure stream?—Yes; but that was taken voluntarily by both sides, because obviously what we wanted to get at was a reasonably fair trial. What they wanted to find out was whether the sludge in itself interfered with the flow of or polluted the river. They knew perfectly well, of course, that lower down the stream there had been many preventable cases of pollution, but it would not be fair for them because there were preventable cases of pollution, which, up to that time, they had not stopped, to urge those cases of pollution against us, because we had never done anything to contribute to them. If they would keep the river pure, then, except for the point which you made, which I have endeavoured to deal with, that is, that matter remaining in the milldam may give rise to some amount of putrefaction (very small, by the way, but may give rise to some putrefaction)—except for that point, if they make the stream clear there would be no question of pollution.

20092. This particular case, Mr. Hughes, does not appear to have been a very strong one; it is a question as to whether the Rivers Board have been well advised in selecting it; because the matters which were settling, which were held back, were matters coming down naturally in an unpolluted stream. You would agree, would you not, that very serious pollution would arise by the holding up of putrescible matters, say, from sewage?—Yes.

20093. Holding these up for months, for a year, or two, before they are discharged wholesale into a stream?—I follow you exactly, but look at the hardship. We will suppose, for a moment that the Rivers Board or other public authority is going to prevent all preventable causes of pollution. Very well, they say during the time that we have not exercised our powers fully, or have not achieved our end, pollution will go into your dams and therefore you shall not sludge. Time goes on and the river has had removed from it all preventable causes of pollution; and you have stopped a harmless process; you have interfered with trade. Why? Because, for a time, the Board or the competent authority, whoever it may be, has not removed the pollution out of the river; in other words, it is the story of the wolf and the lamb exactly.

20094. I am pleased to find that you have a lively faith in the ultimate purification of streams, Mr. Hughes?—As to that, Mr. Chairman, all I can tell you is this: Granted—and I grant it most fully, and so does every gentleman forming this millowners' body; I will tell you why I say that with a confident belief in what I am saying in a moment—granted we all say we want pollution stopped; are wholly in favour of pollution being stopped; but what we also say is this: With regard to a manufacturing river, a river running through a manufacturing district, what is the objective, the end, the aim, of those who desire to make that pure? Is it that they desire, as one of the hon. Commissioners suggested to me a minute ago, talking about fish, that we are going to see entirely removed all causes of pollution in the River Don; that the salmon pastures of Sheffield are again to become salmon pastures? If that is the desire, I do not hesitate to say, as a man of business and as a man of common sense, that it will never be done. The river is the natural adjunct to a manufacturing place. It goes down to Rotherham; it goes down to Doncaster, and then it goes to the sea, without the slightest bit of harm or difference to anybody, whether it is polluted by manufacturing processes or whether it is not.

20095. You say the river is the adjunct to the manufacturing process of a district?—Undoubtedly that river, the River Don, has been one of the causes of Sheffield rising from a little manufacturing village, where a few knives were made, into the great manufacturing place which it is to-day.

20096. But you do not suggest, do you, that the increasing impurity of the river can be an advantage to manufacturers?—I do not say that for a moment, Sir, although I am not going to make it really a strong argument or anything of that kind; but, as a matter of fact—I should almost say it has been a fact, and it is an undoubted fact, that since we took the sewage out of the River Don at Sheffield—quite the proper thing to do, of course—the water plays havoc with the boilers. The acids in the river were neutralised by the alkalies of the sewage actually; and as matter of fact, from the manufacturing point of view, the boilers, beyond the fact that they took some cleaning, did not get bitten and pitted with the acid as they do to-day; and anybody in Sheffield to-day would tell you that the life of a boiler since the sewage was out of the river was less than it was before. But let me go back to the actual evidence; that is only in passing. Take, Mr. Chairman, an ordinary case of an ordinary firm which does not pollute; take Vickers, Sons, and Maxim, or any firm you like in Sheffield who carries on manufacturing processes; what use do they make of the river? If they are upon the river they take the water in; they use it in their boilers for raising steam, and when they have done with it they put it back.

20097. They probably use it for condensing also; do they use it for condensing purposes?—And for condensing, too. When they put that water back into the stream; is it the same water as it went in; is it water that fish will live in? It cannot be; it must of necessity, by reason of the introduction of oil and other things in the water running the boilers—it must of necessity become less pure and less suitable for fish to live in. But which is to survive—the manufacturer, who is giving employment to thousands, the manufacturer who is making England what it is, or are we to go back and make the Don a river in which fish, we will say, will exist from the one end to the other, and the manufacturers on the stream are unable to use it for the purpose of manufacturing?

20098. The point you raise is a very interesting one, but it is somewhat broad and a little way from the special point we are dealing with to-day?—I quite agree.

20099. The special point we are dealing with to-day, and upon which we are anxious to obtain information from you is, first of all, whether any nuisance does, in fact, arise from the sludging of milldams. Now, you are

able, I believe, only to give us information in regard to the sludging of milldams upon an unpolluted or substantially unpolluted stream?—Substantially unpolluted stream, yes.

20100. And you give us as your opinion that no nuisance arises; and that, in point of fact, in your view, no inconvenience arises?—Yes.

20101. But I would like to put this, at all events, to you—you may be in the main right on an unpolluted stream, but I would like to put this to you—that the action of your manufacturers in upholding the waters of such a stream gives as a result: the sending out into such a stream of a large accumulation of suspended matter, which, if it was allowed to go minute by minute, hour by hour, day by day, would not be felt. For instance, it is likely that the suspended matter in that city would not exceed two parts per 100,000 in the natural conditions, except at times of storm. I have in my mind figures in connection with other rivers, not the Don; but it is exceedingly likely that, in times of sludging, the river would for some hours afterwards contain 100 times as much suspended matter?—Just as it does in flood, you know.

20102. It is suggested to us, if it is perfectly innocuous mineral suspended matter, sand, and so on, it will settle in the channel of a stream and only very slowly be washed away; and that the retention even of dead leaves and matters which come down the stream will cause an excess of a nuisance, which possibly might exist in theory, if they went down the stream minute by minute and hour by hour?—I do not think that it is anything like a correct view of what happens in a stream like the Don, to say that it goes down minute by minute and hour by hour, because it does not. The Don is really a mountain torrent. When you say a mountain torrent, you think of something with very high mountains and a very rapid river; but, nevertheless, it is in effect a mountain stream, a mountain torrent. What happens there is this: that the flood takes the stuff down, sewage or whatever it may be, and when it comes to some bend in the river, and the flood is exhausting its power, down goes the material in precipitation, and in the summer, in the dry time, the river itself has practically no flow excepting compensation water from the dams from the waterworks.

20103. Then I gather from what you say that this stream is not so pure as I thought it was; you say it contains sewage?—I was taking sewage; I was coming to this point, that if you take the sewage out, which *ex concessis* must be done, then your cause of offence against the dam is gone; and that brings me back to a thing I was going to say to you about a minute or two ago, except as to the question of decaying vegetable matter, the volume of decaying vegetable matter, as compared with the solid detritus, sand and gravel which comes down the stream, is practically infinitesimal.

20104. And then in your case, speaking generally, the evils of dam sludging are not great?—I do not think so at all; you know, all the way down to the lowest of our works, that is to the bottom of Sheffield, there is no sewage comes in except from certain little rural collections of houses, which are always such a difficulty; you have a certain amount of sewage percolating into the stream. Well, now, in our case that was brought as a possibility of pollution, and, of course, one after the other proved it on our opponent's side, but it was like talking about putting a wineglassful into a big bath, or something of that sort. I mean the thing was too infinitesimal to have any real effect. Below us, of course, there is the problem of the Sheffield sewage effluent, which is giving rise to a great deal of trouble and anxiety to the Sheffield Corporation at the present time.

20105. Then you have no cases of dams on very polluted streams?—No, and I do not like generalising from insufficient knowledge.

20106. The point I want to make is this, that your evidence applies to an unpolluted stream?—Practically.

20107. And that you state your opinion that in such a case the sludging of a dam would probably produce no appreciable nuisance?—It does not, in my opinion.

20108. But you do not want to convey, surely, that in any case dam sludging would give rise to no appreciable nuisance?—No, I do not. I say it is not only my opinion, because we have been, as I say, through the sworn testimony in three Courts. Take the last Court, which was careful enough, the Divisional Court, that examined the matter very carefully; it is all down on sworn testimony that there has been no pollution. But take your case of a river which is polluted with sewage; just let us suppose for a moment that there was a large town at the top of the Don delivering large masses of crude sewage into the stream, would anyone think it would be a fair thing to impute to the process of sludging the fact that the pollution went on down the river at each sludging? Surely the answer would be:—Remove the source of the evil above; take the sewage out of the stream, as you have ample powers to do, and then there would be no sewage in the dams.

20109. Yes, but the whole thing would turn on this, would it not, whether—by withholding these matters and letting them accumulate for months, and it may be for a year or two years, and then turning them out wholesale within a few hours into the stream—you are not condensing the nuisance into a very short period, which, allowed to spread over the whole period, would scarcely have been appreciable?—Well, you are asking me, of course, now about something which I have no means of measuring. Just suppose for a moment that Sheffield was sending the whole of its crude sewage into the river Don and passing it down through Rotherham, and that in between the two places there was a mill dam, and that that mill dam was sludged at intervals of a year. Well, I should say that it would make no appreciable difference whatever. I should say that the nuisance of the crude sewage in that stream going down was the real nuisance, and the fact that you sent a few hundred tons or so of material, some of which was sewage, down that stream would not have any real effect in adding to the real difficulty, which would be the passing of the crude sewage of Sheffield in this stream going down to Rotherham.

20110. We take that as your opinion; but you are probably aware, are you not, that grave complaints have been repeatedly made, say, to the West Riding Authority, which you have referred to, in connection with the evils of dam sludging; that the matter has received attention in other parts of the country; that papers have been read at Sanitary Institutes calling attention to the serious evils caused by these things. You are probably aware that there is another side to the question?—I am quite aware that there is another side to the question; but, of course, I am here to answer for the river Don. I do not know what would be the effect of sludging a mill dam in a comparatively still water; but then, on the other hand, I fancy that the conditions of the river Don would apply in the case of other rivers, because from the nature of the things you cannot have these mill dams supplying power on any streams except rapid streams.

20111. Then we are to take it, reiterating what we have been talking about for some time, that in connection with this stream, which is substantially a pure stream, in connection with works which themselves do not turn out trade effluents, for the most part no serious evil, in your opinion, arises from the sludging of the dams?—No.

20112. Then the next question comes, suppose there was an alteration of the law brought about to put under the control of Rivers Boards, or other authorities, the sludging of these dams, would that, do you think, be considered to be an evil by your association; would it hurt them to any important extent if they were obliged to let off those dams at certain periods to be selected, or at times of storm, or times of holidays, and so on?—Would you kindly look at this, which I will hand in. (Document handed in.) I mentioned in my proof I would hand it in.

20113. These are regulations by your association?—These are rules as to sludging out of dams adopted at a general meeting of the Don millowners, held at the Cutlers' Hall, on Tuesday, 29th June, 1898.

20114. Then your association has imposed upon its members conditions?—Our association has imposed upon its members voluntarily conditions which were considered to be reasonable in connection with the sludging of dams.

20115. Your association already recognise that in connection with dam-sludging if certain conditions are not fulfilled evils may arise?—Yes; but I rather think, if you will allow me to say so, that the question to which we addressed ourselves was not the question of pollution, which practically, in my opinion, does

Mr. Herbert Hughes, C. M. G.

8 Dec. 1904.

not exist, but it was to the effect with regard to a large mass of solid matter interfering with the flow of the stream. Supposing a man, for example, did not sludge out his dam for five, six, seven, or eight years, and then sludged it out, it would stand to reason that there would be an enormous mass of materials to go down; and not only would he affect the stream by sending an enormous amount of solid matter in suspension down, but he also would affect every other millowner below him whose shuttles would be open. They would know nothing about when he was going to do it; their shuttles would be open, and in would go this mass of material, and the thing would have to be done three or four times over, which would be a wrong thing. The consequence was we put ourselves into the voluntary harness in order to insure reasonable protection. For instance:—

1.—All dams upon the streams should be cleaned out every year.

2.—The time for sludging out dams should, if possible, be during holidays or general stoppages; but no dam should be sludged unless there is a good flow of water in the main stream."

The object of that, of course, being partly to prevent the other dams being made receptacles of the sludging of the first, which would be to do the work three or four times over—well, 30 times over if it went all down the stream; and on the other hand on the part of the public that there should be a good flow of water on the stream, so that it should not be clogged up by solid matter:—

3.—As much water as possible should be passed through the dam at the time of sludging, so as to carry it away rapidly and in as fine particles as possible, and the work, when once commenced, should be carried out expeditiously.

4.—Information must be conveyed 48 hours before sludging a dam to all the millowners down the stream within a distance of five miles, and to the manager of the River Don Navigation, Corn Exchange Buildings, Sheffield.

That is because they have an intake in the dam for the purposes of their canal. Of course, they are in the same position as an ordinary millowner; they do not want their shuttles open when material is going down, because they would have to clear it out again.

5.—In case these rules are not generally adhered to by any millowner, he shall not be entitled to be defended out of the funds of the millowners in case a summons is issued against him for sludging his dam.

Well, now, we put ourselves in that position. Now let me answer your question. Any regulations in reason as to how dams should be sludged will be cheerfully accepted by the millowners' body. I have told Mr. Trevors Edwards, who is the solicitor to the West Riding Rivers Board, that the moment he abandons the position which he is taking up, his Board are taking up, of abolishing sludging altogether, which would mean abolishing the water power altogether, and says:—"Now, how can we put our heads together; how can we best sludge out the dams; can we say that a year is too seldom; do it once in six months, or something of that sort." We should immediately become responsive. We should welcome anything of that kind, granted that dam sludging, which is the only practicable means of getting rid of this detritus, which comes to us down the river in the natural way is admitted. Granted that is admitted, that we have a right to get rid of it in the old, ancient way, with no harm to anybody, never having created an epidemic, or even a single case of illness, so far as we can find out, we are willing to have such regulations as may be reasonable, that would cause the least inconvenience to millowners on the stream and everybody concerned.

20116. Then the fact that your Association have agreed to submit themselves to these regulations, that you yourselves have drawn up, I think may be taken as proof by this Commission that in the absence of some control, self-control in this case, but in the absence of some control dam sludging may be a serious evil?—It may be an inconvenience.

20117. Well, put it that it may be an inconvenience?—You see, Mr. Chairman, may I differentiate between pollution and the other thing that we have got to avoid—that does not so much concern you, although it very much concerns us—the interference with the flow of the stream. These regulations are aimed to prevent just this. Two or three people might sludge their dams together at a time of dead low water; that material might go down the stream, and by reason of the stream not flowing at any rapid rate it would be precipitated, creating sand-banks—that was tried to be alleged against us—and so forth in the stream. Well, our object is to avoid all that, and also to avoid that we are sludging our dam, getting rid of our solid matter and sending it down the river in a state of suspension just as the river does when it is in flood to our neighbours' detriment, and to ensure that the other people down below should close their shuttles so that they should not have any portion of it coming into their dam, as they would have to repeat the process at a later date.

20118. In short, for dam-sludging some control is necessary?—I think it is desirable in the interests of everybody concerned in the river; but in the interests of the prevention of pollution I do not think any control is necessary, because I do not think, in a properly regulated stream, there would be pollution worth speaking about in the sludging of the mill dam.

20119. And we are to gather, are we, that if some reasonable control is in the hands of such bodies as Rivers Boards, you think that the manufacturers would willingly submit to reasonable conditions?—If, with all respect to the Rivers Board, I might suggest that there was an appeal to some body. I am not myself filled with admiration as to the moderation of the West Riding Rivers Board. On the contrary, I regard the West Riding Rivers Board, under its present policy, of being a body—I must say nothing offensive—of a distinctly interfering kind.

20120. Naturally; it is the nature of their business?—For my part, I think the West Riding Rivers Board would pursue their ideal to the extent of enabling boys to catch trout in the confines of the City of Sheffield, and would not care a little bit if by doing so they had to interfere, as they would interfere gravely, with the trade of Sheffield, and put an additional shackle on people already shackled badly enough in their struggle for life in trade in competition with other places.

20121. I am afraid the policy of the Rivers Board is not before us to-day. They cannot carry it out of necessity unless they interfere with somebody?—Mr. Chairman, you asked me if I would leave it to the Rivers Board. No, I would not. I think we need not go into that subject, but some body, probably the Local Government Board, should have a voice in the matter, or on appeal, as to any regulations. Then, by all means, if it is thought that regulations, further than those we have made, should be adopted, let them be put forward.

20122. Are you familiar with the Third Report of this Commission, in which a suggestion was made that in connection with trade effluents, for instance, there should be in the first instance an appeal to the Rivers Board, and from the Rivers Board to a Central Authority in London?—Yes.

20123. Then such an appeal would meet your difficulty?—It would meet the difficulty of regulation only. Mind you, I do not give way on the question of regulations unless it is admitted that the dam sludging is to go on. I mean to say the dam sludging, subject to regulations, yes; regulations which would abolish dam sludging, no.

20124. You mean that under no circumstances would your Association desire to consent to removing the sludge in carts or barges on to land; is that what you mean?—All I have to say about that—I am glad you have mentioned that now—is this: It is as absolutely impracticable as anything could possibly be. Take the City of Sheffield, now; take the works in the City of Sheffield which have refuse to get rid of, furnace slag and so forth. What happens to it? Well, it has to be carted, perhaps, from two and a half to three miles from the works. When it gets to its destination it has to be deposited at a cost of from 6d. to 9d., and in some cases 1s. per cubic yard. Practically speaking, it would be absolutely prohibitive; you would not be able to use your water-power if you had to remove the proceeds of this; which, of course, in this instance is really the natural detritus coming down the stream. The weight of material which requires to be moved would be immense, not harmful material, but the ordinary sand and detritus that comes down the stream.

20125. But you say it would be impossible—I suppose financially impossible—for a manufacturer to remove the sludge from his mill dam, but, as a fact, does

not almost every manufacturer have to cart away his ashes from his boilers?—Yes.

20126. And trade detritus of a solid kind?—Yes; but the power you get from the dam is somewhere about 40-horsepower, we will say; there is horsepower that does not cost you anything. If you remove the detritus brought down by the alluvial stream to the land from your dam you will be removing a very large amount of material as compared with the 40-horsepower, as compared with the ashes and slag and so forth from a 40-horsepower engine.

20127. Do you suppose it would be more?—Undoubtedly it would be more.

20128. Why, it would only have to be moved probably once in a year or once in two years?—I honestly wish that the Commission could not just have to hear what I have to say, but would come and have a look at a mill dam when it is sludging out and see the masses of sand and material that have to go down the stream just as it is brought by the stream. I assure you it is a very difficult problem, and it was attempted in evidence in our case to be proved by the West Riding Rivers Board, by way of showing that what they were doing was not unreasonable, that we could remove this material, and that it would cost us very little to do this, while the fact was just the opposite.

20129. As a fact, in many cases it is so, is it not; possibly not in your district, but in others?—As to that, unless I absolutely know the circumstances, I should not like to pass an opinion. What I do know is this, that the waters of the River Don give us free power to the extent, perhaps, in some instances, of 40-horsepower free. I say that if upon the advantage of that you put the difference between sending men into the dam to loosen the stuff, and letting the river, as it will, carry it down, and the carting of the material from the dam to carts to take it away from the place a long distance, and the money you have to pay to deposit it, I simply say that it would kill the water power, that is all. And what I ask the Commission is this: As I said before, I am, and so are these millowners that I act for, absolutely in favour of stopping anything which puts human life in peril or brings sickness, but what we ask you, and any body of gentlemen who are addressing themselves to the subject, is this: If it cannot be proved that the sludging of the dam produces illness, sickness, or some other thing which is not consistent with trade, why should you interfere with trade to the extent of abolishing dam sludging which does no harm? Now, let me put to you why I say my people are in earnest in that. You are, I dare say, aware that we are largely dependent for water power on the supplies of water—called "compensation water," which is provided by Statute; public bodies impound the water as Dewsbury, Barnsley, and Sheffield have done—Sheffield's "compensation" from the Loxby and Nevelin watersheds being as much as 9¼ million gallons a day, we are dependent upon that water, but never once have the millowners refused to give up that supply in times when they wanted it most—for a consideration, of course, but to give it up when it was worth a great deal more to them than anything they got for it, because of the domestic needs of the people. Now, on that we have always given way, and always recognised the domestic needs of the people for water.

20130. I do not think it is a matter so much of sickness, as of inconvenience. For instance, the manufacturer below on the stream, your regulations imply that there is inconvenience of that kind unless proper precautions are taken?—Yes; inasmuch as the detritus goes into other dams.

20131. Your evidence is largely limited to a stream which is almost unpolluted, and I do not know that I need keep you longer by asking you any more questions?—I should just like to say one thing, and that is this: There are a great many dams; as you will see, they are printed here; here is a list of the works which are on the Don; you will see the number of people who are using this water-power over and over and over again. You can imagine how valuable it is when you look at the list of names. Well, now, dam sludging has gone on up to the present time. I have never heard, in the whole of my twenty-eight years' experience in Sheffield, any complaints whatever on the part of the people who were taking in the waters of the Don for engine purposes in Sheffield, of which there are a large number, of any inconvenience whatever caused by solid matter in suspension, arising from the sludging of dams.

20132. But surely that is due to the regulations under which your association works?—Precisely; and, as I told you, I would not object to regulations of that type.

Mr. Herbert Hughes, C.M.G.

8 Dec. 1904.

20132A. Before asking my colleagues if they have any questions they would like to ask you, I may mention incidentally this: I know a little of the subject before us, that the waters of the Don were generally acid, and that the alkalis used in connection with sewage treatment had their utility. That acidity is largely due, is it not, to the sending into the stream of water from mines?—Well, the ochre water has some effect.

20133. Is it not mainly due to the ochre water, or is it to the pickle?—I should rather be inclined to think that it was material from the wire mills—which had a good deal more to do with it, the acids from there. You will remember some time ago there was a great scare about lead-poisoning. It is a peculiarity of water undeniably pure which comes off the moors in our neighbourhood that it does contain a quantity of acid, and that the acid will take up the lead from lead pipes, and therefore also attack other metal, and that that has to be neutralised, as it is neutralised by the adding of chalk, and so forth; so that practically you have got a state of things arising with the pure water which is drunk by the people of Sheffield, and which is as near purity as you can possibly get, because it is nothing but water running off moorland into the reservoirs. That water carries acid with it, and if it is not neutralised by chalk it will take up the lead of the pipe and produce lead-poisoning.

20134. So that you have three sources of acid?—Yes.

20135. The natural source of the moorland waters?—Yes.

20136. And the ochre water and the effluent from the wire?—Yes. I thought you had heard of it, because it led to a scientific discussion. Many causes were alleged as to why the water was acid and why it took up lead.

20137. *(Mr. Stafford.)* Have you had any analyses made of this sludge?—Oh, yes; very careful analyses have been made with the view of proving that it is polluted, and those analyses were put in proof in our case. Analyses by the whole of the staff of the Rivers Board and the County Council were taken most carefully. They had bottled the effluent as it went down while the sludging was going on, and brought that evidence before the Courts.

20138. What was the result of these analyses?—It did not prove pollution. It was all right from appearance point of view. They shook up the bottle, and it went rather black-looking, and that was supposed to create an effect, but the analysis utterly failed to show that it was polluted.

20139. Do you hand in any of these analyses in your statement?—No, but I should think you could get at them. The proceedings in the case would be open to you. I should be very pleased, indeed, if the Commissioners would like it, to send them the shorthand notes. I have only one copy—they could easily have them printed if they wanted to—of the trial before the Quarter Sessions which raised the facts, and you will see the facts.

20140. It might be interesting to have the analyses ———*(Chairman.)* We could get these from the Rivers Board?—It does not matter whether you get it from the Rivers Board or myself. We had a joint shorthand note.

20141. You tell me the pollution was not proved?—Oh, no; if it had been ——

20142 Do you assume that is so because the prosecution failed?—That is the only ground upon which it could fail.

20142*. Was there not another ground—that there is an exemption, is there not, in connection with the Rivers Pollution Act, if you merely send down what belongs naturally to the stream?—One moment, Mr. Chairman. You may send down the natural detritus, but listen to this proviso—this is what we were attacked upon:—"Provided that the sand or gravel or other natural deposit so put back or carried as aforesaid does not interfere with the due flow of or pollute the water of such river or stream." So that if they could have proved pollution—it was what they tried to prove

Mr. Herbert Hughes, C.M.G.

8 Dec. 1904.

—or if they could have proved interference with the due flow, which they also tried to prove, we should have failed; but, as a matter of fact, they tried to prove them both, and failed to prove either; therefore we got our case.

20143. *(Mr. Power.)* Apart from obstruction or pollution, was there any evidence produced that people had suffered disadvantage from the sludging?—No; that disadvantage is legitimised by the Act if there be a non-polluting discharge.

20144. I mean riparian people?—No, I have never heard. No; there was no case made of that sort. so far as I know.

20145. Is there another river Don in the West Riding which is connected in any way with Heckmondwike?—Not in the West Riding, so far as my knowledge goes. There is the Little Don, which is a tributary to the Great Don; that is the river on which Sheffield has made its new waterworks.

20146. The Don flows, after leaving Sheffield, through Rotherham and Doncaster?—Yes, and down into the Trent, and from the Trent into the Humber.

20147. Oh, that way?—I think so. I will not be absolutely certain, but if you had asked me some time ago I should have been familiar with it, because we had a case in which the point occurred. The Don runs into the Trent, and the Trent runs into the Humber. I think that is the course of the river.

Statement handed in by Mr. Herbert Hughes, C.M.G., Clerk to the Don Millowners' Association.

RIVERS DON, LOWER DON, AND LOXLEY MILLOWNERS.

Rules as to Sludging out Dams, adopted at a General Meeting of the above-named Millowners, held at the Cutlers' Hall, Sheffield, on Tuesday, the 28th day of June, 1898:—

1—All Dams upon the stream should be cleaned out every year.

2.—The time for sludging out Dams should, if possible, be during holidays or general stoppages, but no Dam should be sludged unless there is a good flow of water in the main stream.

3.—As much water as possible should be passed through the Dam at the time of sludging, so as to carry it away rapidly and in as fine particles as possible, and the work, when once commenced, should be carried out expeditiously.

4.—Information must be conveyed 48 hours before sludging a Dam to all the Millowners down the stream within a distance of five miles, and to the Manager of the River Don Navigation Corn Exchange Buildings, Sheffield.

5.—In case these Rules are not generally adhered to by any Millowner, he shall not be entitled to be defended out of the funds of the Millowners in case a Summons is issued against him for sludging his Dam.

Dated this 5th day of July, 1898.

Herbert Hughes, Clerk to the Millowners.

LIST OF MILLS AND WORKS ON THE RIVERS DON, LITTLE DON, AND LOXLEY, TOGETHER WITH THE NAMES OF OCCUPIERS.

RIVER DON.	RIVER DON—*continued.*	RIVER LOXLEY.
Bullhouse Mill, Penistone. Goldthorpe and Hinchliff.	Beeley Wood Steel and Iron Works, Wadsley. Henry Burkinshaw.	Bradfield Corn Mill, Bradfield. J. Crapper.
Millhouse Works, Penistone. W. Smith.	Clay Wheel, Wadsley. Thos. Firth and Sons, Ltd.	Storrs Bridge Forge, Loxley. Swift Bros.
Eckland Bridge Works, Penistone. W. Hoyland and Co.	Niagara Forges, Wadsley. A. Stringer.	Old Wheel Steel Works, Loxley. Thos. Wragg and Sons.
Plumpton Mill, Thurlstone. Thos. Tomasson and Sons.	Marshall's Forges, Wadsley.	Ashton Carr Mill, Loxley. C. V. Bunting.
Thurlstone Corn Mill, Thurlstone. F. Booth and Son.	Wardsend Steel Works, Wardsend. Wardsend Steel, Company.	Rowell Bridge Wheel, Loxley. Pitchford and Elliott. W. Williams.
Thurlstone Oil Mill, Thurlstone. W. Whiteley.	Old Rolling Mill, Owlerton.	Olive Paper Mill, Loxley. B. Swift.
Nether Mill, Penistone. Goldthorpe and Hinchcliff.	Old Park Corn Mill, Owlerton.	Little Matlock Works, Loxley. Kenyon Bros. and Co., Ltd.
Oxspring Wire Mill, Penistone. G. Winterbottom.	Old Park Silver Mill, Neepsend. Old Park Silver Mills Co., Ltd.	Green Wheel Tilt, Loxley. C. V. Bunting.
Oxspring Corn Mill, Penistone. Thomas Dransfield.	Clifton Steel Works, Neepsend. Jno. Hy. Andrew and Co., Ltd.	Glass Tilt, Loxley. Pattinson and Co.
Old Wire Mills, Thurgoland. Jagger Brothers.	Philadelphia Steel Works, Penistone Road. Burys and Co., Ltd.	Loxley Steel Works, Loxley. H. Denton.
New Wire Mills, Thurgoland. G. Wordsworth and Sons.	Britannia Corn Mills, Alma Street. H. & W. Ibbotson.	Wisewood Forge, Loxley. J. Wood and Sons.
The Tilt Mills, Thurgoland. Joseph Dyson and Co.	Millsands Works, Millsands. Sheffield Forge and Rolling Mills Co., Ltd.	Wisewood Rolling Mill, Loxley. J. Wood and Sons.
Upper Forge, Low Forge, and Tin Mill. Thomas Andrew, Wortley Iron Forges.	Wicker Tilt and Forge, Wicker.	Malin Bridge Wheel, Malin Bridge. German Wilson.
Deepcar Mills, Deepcar. John Armitage and Sons.	Wicker Wire Works, Blonk Street. J. G. Cocker.	La Plata Works, Malin Bridge. Burgon and Ball.
Dyson Holmes Forge, Oughtibridge. Josh. Rodgers & Sons, Ltd., Norfolk Street.	Don Steel Works, Savile Street. Francis Hobson, Seaman, & Co.	Limerick Wheel, Malin Bridge. Ward and Payne.
Spring Grove Corn Mill, Oughtibridge.	Royds Mill, Attercliffe. Thos. Marrian and Co., Ltd. Edwin Whitton.	Owlerton Wheel and Wire Mills. Woodsworth and Sons.
Spring Grove Paper Mills, Oughtibridge. P. Dixon and Sons.	Attercliffe Steel Works, Newhall Road. Sanderson Bros. & Co., Ltd.	Nether Owlerton Wheel, Owlerton. S. Laycock and Sons, Ltd.
Oughtibridge Forge, Oughtibridge. A. Blackwell.	Brightside Works, Brightside. W. Jessop and Sons, Ltd.	Owlerton Old Paper Mill. S. Laycock and Sons, Ltd.
Oughtibridge Low Tilt and Corn Mill.	**LITTLE DON.**	Birley Meadow Tilt, Owlerton Denton and Best.
Middlewood Iron and Steel Works, Middlewood. S. A. Parkin.	Midhope Corn Mill. Herbert Woodhouse.	Upper Slack Works, Owlerton. D. Doncaster and Sons.
Middlewood Forge and Rolling Mills, Middlewood. George Clarke.	Stocksbridge Works. Saml. Fox and Co., Ltd.	Nether Slack Works, Owlerton. Thompson Bros.
	Henholme Pipe Works, Deepcar. J. Armitage and Sons.	
	Deepcar Mill.	

J. Selwyn Rawson called in; and Examined.

Mr. J. Selwyn Rawson.

8 Dec. 1904.

20148. *(Chairman.)* You are a millowner?—Yes.

20149. On the river Don?—The river Ryburn.

20150. Which flows into the Don?—No; it flows into the Calder; it has no connection with the Don.

20151. Where is your mill?—It is upon the stream above Sowerby Bridge.

20152. You have no connection with the Don?—No; it is a different district altogether. It really starts on the Pennine Range, higher up on the Blackstone Edge Range.

20153. Then the stream on which you are situated is the——?—The river Ryburn.

20154. And that is a tributary of the Calder?—That is a tributary of the Calder.

20155. Then is that stream, as it comes to your mill, substantially a pure stream, or are there dams above you?—There are dams both above and below.

20156. Is there any sewage coming into the stream above you or any trade pollution?—There is very little trade pollution, but in the evidence that was given in our case when we were prosecuted by the Rivers Board it was stated that there were 490 cottages which drained into the river.

20157. Above you?—Above us. I am not here to dispute that; my own evidence was that there were 120.

20158. It is immaterial?—It took a larger range.

20159. You agree there is sewage coming into the stream?—Yes.

20160. And therefore by impounding the waters at your mill you are holding up something of the sewage or suspended matter which otherwise would pass down into the stream?—Yes, we are holding up a certain quantity; we must do.

20161. Now, do you suggest by doing that you do not cause any evil to arise, first of all in your dam and afterwards in the river in times of sludging?—No; I do not think so.

20162. You absolutely hold, do you, that no evil is produced?—Yes; we never have had any complaints. From the mills above we have never found anything to complain about, provided they did, as it seems the Don millowners do, sludge at holiday times and give the lower millowners notice.

20163. *(Mr. Power.)* What is the next nearest to your mill, of the mills below you?—Major Morris's.

20164. How far?—If I might explain; the mill that we were prosecuted for is not my mill now. My brother and I were running it, and we have since given up manufacturing, and it is not used now. That was the Thorpe mill dam, the next mill dam below us was Morris' dam, which is about a quarter of a mile below; then, again, after that I have a mill dam which is about 200 yards below that, and then about another quarter of a mile below my cousin has another mill dam, so we are all on the same stream.

20165 The dam of your disused mill will now be shut off from the river, or will that continue to be sludging up?—No, it is disused for anything except running a dynamo.

20166. *(Chairman.)* If you had a mill dam immediately below you, you would think it necesary to give them notice when you were to sludge?—We always did; as a matter of courtesy we used to two miles further down the river, as far as Sowerby Bridge.

20167. Then a temporary evil does arise, and you think it necessary to warn persons down a stream to close their valves?—The evil would arise from the fact that below our mill dam, at the next mill they have a mill weir, and if we did not sludge in a holiday time, or if there is very little water going down the river, all our sludge, or, at any rate, a considerable portion of it, being so close together, would pass into their dam.

20168. So it is necessary to have some control?—I think so.

20169. You agree that some control is necessary?—Oh, I do not dispute that at all.

20170. Are we really to take it as your deliberate opinion that the upholding of these matters, partly sewage matters, in the mill dam, produces a sludge which is innocuous, which is likely to give rise to no nuisance at all, even if let out at long intervals and large quantities?—If I might go back——

20171. We will take that from you if it is your view?—Oh, yes, it is so. I was only going to say, if I might go back 30 years, we used in those days to sludge our dams, as a rule, once every three or four years; not every year, and the river was full of fish; we never found that it damaged the fish in any way; to-day there is no fish in the river.

20172. *(Mr. Power.)* Were the dams sludged, many of them simultaneously?—No; I do not think so.

20173. Or in regular order?—No; I do not think so, because we should, perhaps sludge once in three years, and we usually did it at holiday times.

20174. What is the effect of giving notice; is it not that perhaps all mills sludge their dams at once and the same time?—Oh, no, not at all.

20175. *(Chairman.)* Then, though you have not had any complaints, you say, in regard to the sludging of the dams, which you no doubt carry out so as to avoid as far as possible producing any evil, you know that on other streams there have been serious complaints of dam sludging, do you not?—Well, I could not say anything about that. I do not know that any millowners have ever complained to us, and I never heard of any doing so on our stream.

20176. But you recognise that it will, temporarily at least, largely increase the suspended matter in the stream if you sludge out a dam which has not been cleaned for a year or so?—It will for a mill possibly down the stream.

20177. And you recognise the necessity of some control of dam sludging?—I do not think there would be any harm in it, supposing there was reasonable control.

20178. As a fact, nobody has any control of dam sludging at present?—No; they have not.

20179. And you think it would be reasonable that somebody should be given such control?—I think so.

20180. Would you be satisfied to place it in the hands of the Rivers Board, subject to appeal to a Central Authority?—Yes, I think so; subject to appeal. The Rivers Board, I know, are a very hardhearted body.

20181. *(Mr. Power.)* Have you at present on your stream any general rules governing sludging?—No; none whatever. We have no Millowners' Association on our stream.

20182. *(Chairman.)* At present there is no control?—No; none whatever.

20183. You think that control is reasonable?—Yes; we have never had any case of complaint from our neighbours.

20184. If damming sludge were prohibited, and you were compelled to remove your sludge in carts or barrels on the land, would you consider that would be a prohibitive expense for a manufacturer?—Well, in two instances. In one instance, the mill dam above the Thorpe dam, it will be an impossibility almost.

20185. In certain cases?—Yes.

20186. But in many cases it would be possible?—My own dam it would be almost impossible to remove it, because on the one side there is a precipitous rock you could not get up or down; in fact, it is cut out of the side of the hill almost, and on the other side there is a bank which is too narrow to get a cart and horse up between the stream and the mill dam. The dam is a matter of 200 to 300 yards long and 60 yards wide.

20187. Then, in such case where, owing to the local situation, it would be very costly to cart away the material, you would suggest that it would be better to let off the dam much more frequently?—Well, we do let it off as frequently as possible on Saturday afternoons.

20188. That is the remedy you suggest, is it not?—Oh, certainly.

20189. *(Mr. Power.)* Have you not an alternative—namely, dredging from a flat-bottomed boat and conveying off the material to one end of the pond and there loading it into a cart and carrying it away. That might be possible under such circumstances as your mill dam?—It would be an enormous expense, I am afraid.

20190. Do you think it would?—I think it would.

20191. It is done, you know, constantly in navigable rivers?—I know it is in rivers.

20192. In rivers and mill dams in some parts of the South of England it is very frequently done. It is done pretty frequently, not waiting five or six years. It has the advantage that it does not send large masses of suspended matter down; it takes a great deal of it out?—I have never seen it done except dredging in harbours.

20193. I do not know the relative cost of dredging compared with that of running sludge away?—Suppose we had to take and wheel this out. Of necessity before you could wheel it the mill dam would probably have to be emptied, and remain empty for a week or ten days, because it is quite thin, and it would require to stiffen before it could be dug or wheeled, so that it would, in the first place, mean closing the works for a week or ten days, and then I should say it would probably take nearly a fortnight to empty any of these mill dams by wheeling out.

20194. The dredging plan from a punt would be preferable in that it would not stop the works?—If it could be done, certainly.

20195. If it could be done?—In this Thorpe mill dam, at the end where it discharges into the river, the lower end, it is about 15 feet below the bank, so that would all have to be either lifted by a steam crane or else wheeled up from steep planks.

20196. (*Chairman.*) There are many cases where it is quite possible to do this, are there not?—To wheel it out?

20197. Yes?—Oh, there are, certainly.

20198. Where there is adjacent land?—Yes, certainly; if it were possible to wheel it out at a reasonable cost I would wheel it out myself.

20199. You think that would be a proper thing to insist upon where practicable?—Except for the expense; as I say, having to close the works down for two or three weeks.

20200. (*Mr. Power.*) It has some value as manure, has it not?—Certainly; I should be very glad to get the whole of it out for my own land, very glad indeed, if it could be done at anything like reasonable cost.

20201. (*Chairman.*) Would it not be possible to pump the sludge?—Oh, no, it would be too stiff.

20202. Instead of leaving it empty for a fortnight in order to dry this material and then another fortnight empty while you cart it away, would it not be possible to pump the sludge out without emptying the dam?—No; it would be too stiff; you could not pump it.

20203. Would you give us your opinion upon another suggestion which has been made to us, that it is possible to construct the bottom of the dam inclining to a well, and to let pass away from the bottom of the well under pressure of the water in the dam certain quantities of sludge at frequent intervals?—Oh! the sludge would never reach the well. Take Thorpe Mill, with which I am best acquainted, as I have lived there 30 years, in that case, at perhaps 60 yards from the top, there is nothing but sand, pure river sand; in fact, we have wheeled out thousands of tons. We used to wheel out hundreds of tons a year. There was a very ready sale for it, and after a flood a large quantity was always brought down of pure river sand, and we used to draw the dam off on Saturday afternoon and holiday times and put a lot of men in and wheel it on to the bank, and we had a very ready sale for it at 1s. 6d. to 2s. a cart-load. Men would fetch it at that for building purposes.

Mr. J. Selwyn Rawson.

8 Dec. 1904.

20204. It would seem, then, that this carting away in that particular case was very practicable?—That was at that end; that was about 60 yards from the top. Then you came down, further down to the sludge, and when you got to about 60 yards from the entrance from the stream it tails off into ashes and anything of that sort, and then into fine sludge, and, of course, as you get lower down the mill dam was considerably wider and considerably deeper; it was only at the top end where the sand settled.

20205. Then, in impounding these waters you do so, of course, for the advantage that arises from that to you?—Oh! yes, certainly.

20206. That advantage is of considerable value, is it not?—Yes, it is.

20207. And it seems fair enough, does it not, to attach certain responsibilities?—On the one hand we get the benefit; we get the pull, as we say, over the people down nearer Halifax by having water-power, but, on the other hand, we are so far out into the country that the cartage of coals for the engines and the cartage of goods, and general expenses come to more, so that if it were not for that we should be at a great disadvantage.

20208. Well, briefly, your view, then, is that in your district the sludging of your dams has not given rise to serious complaints, that you think some control of dam-sludging is reasonable, that you would be ready to entrust that control to the Rivers Board with an appeal to a Central Authority, and that in those cases where it is not practicable to remove by carting, the best thing to be done is to frequently empty the sludge?—Yes. I may say that the millowners, as a rule, do usually draw their dams—I do not say sludge in the usual meaning of the word sludge when I am speaking of sludging, but—draw their dams off at holiday times and when there is plenty of water, and then turn on 30 or 40 men with spades or rakes and rake it into the stream as it passes through.

20209. That is just what is complained of, of course?—Well, what a good many of the millowners do is this: Whenever there is a fresh on a Saturday afternoon, when they can allow the mill dams to be drawn off, they open their shuttles and let the whole of the water through, because naturally the more water we can collect in the mill dams the greater horse power we get, so it is beneficial to keep the dams as clean as possible. We do that for our own benefit. But still the water then in those cases makes one or two defined channels through the mill dam, and the sludge, which, of course, has been in suspension, settles over the whole of the dam, so it does little more than wash out these defined channels.

20210. The rest is pulled in?—The rest is pulled in at the sludging time. I should like to say, as I said before, that there used to be a large number of fish in the stream, and there would be to-day, I believe, were it not for the fact that there are paper works. It is the paper works that have caused the fish to be done away with altogether. There are some paper works started up above us. Of course, that is another matter.

MR. A. F. SOMERVILLE called in; and Examined.

20211. (*Chairman.*) You are the chairman of the Sanitary Committee of the Somerset County Council, and have been so for some years?—Yes, since 1894.

20212. And you have some personal experience in the neighbourhood of your own home, I believe, of the evils caused by dam-sludging?—Yes; unfortunately I have.

20213. Would you tell us: you have, I think, in the stream above you several of these dams, have you not? But, first of all, you are on the Doulting stream?—Yes.

20214. And that is three miles from Shepton Mallet?—The Doulting stream, the Ordnance Survey people called the Sheppey the other day, which they had no reason to. The real old name of it is the Doulting Water, the Doulting stream. It is marked in the map as the Sheppey—that is a new technical name. The source of the stream is one mile above Shepton Mallet.

20215. One mile above Shepton Mallet; it is quite a pure stream?—Yes; quite a pure stream.

Mr. A. F. Somerville.

8 Dec. 1904.

20216. The first dam is at Shepton Mallet?—Yes.

20217. The first dam is at Shepton Mallet?—The first one of any size is at Shepton Mallet, and I think that is the only one there which is used now, and one below Shepton Mallet, at Bowlish, which is a hamlet of Shepton Mallet, and then there are two in the village of Croscombe; so there are four altogether.

20218. And although the stream above Shepton Mallet is substantially a pure stream, there is considerable pollution from sewage in passing through the villages from Shepton Mallet downwards?—They have got a sewage farm at Darshill, the effluent of which goes into the stream, but the effluent is very much better now than it used to be.

Mr. A. F. Somerville.

8 Dec. 1904.

20219. But there is also some crude sewage from cottages?—There is a certain amount of crude sewage from houses in Shepton and Croscombe.

20220. We may take it there is some crude sewage and some sewage effluent, perfectly or imperfectly purified?—Another sewage pollution, very serious pollution, is the large amount of droppings on roads. That road between Shepton and Dinder, where I live, is a road which is largely used for driving cattle to market, and there is a good deal of horse traffic on it too.

20221. In times of rain?—In times of rain all this is carried down into the stream.

20222. Tell us what you find from your experience to be the effect of the holding up of the waters of the stream and the accumulation in the dams of the suspended matter coming down?—So long as the hatches are down, of course, the suspended matter is precipitated—we get the water fairly pure.

20223. No nuisance arises from the dams themselves except at the times of sludging?—No, oh! no; it is rather the other way, you see.

20224. They help to keep back matters brought down by the stream?—Yes.

20225. They are really precipitation tanks?—They are precipitation tanks, and the stream being pretty rapid below, the amount of pollution which arises in these dams from the deposit of sludge is removed by the passing of the water in a rapid way down the stream.

20226. Then if these dams were emptied so as to bring about the removal of their sludge on to land there would be a positive benefit to the neighbourhood?—Oh! yes; certainly.

20227. But as a fact that is not done scarcely?—No.

20228. And the sludge is pushed into the stream at long intervals?—Yes, that is what I complain of. I have been listening to the replies of the two last witnesses, and I was very much amused at one remark the last witness made. While I think of it I should like to refer to it. He said there was no pollution in the deposited matter in the dam, and yet at the same time he considered it was very valuable matter to put over his land. Now the two things do not agree. If there is no pollution, if the matter is not a polluting substance, it is absolutely useless when you take it as a manure, and the fact that it has a manurial value and contains ammonias which make it, of course, of value to put into the land, proves that the sludge is a polluting substance.

20229. If there is organic matter present?—Yes.

20230. Then what kind of nuisance has arisen from the sludging of the dams in your district?—Chiefly this, that the times when they sludge are the holiday times. The holiday times are the driest times of the year, when the river is at its lowest, and the result is that of late years they take advantage of these holiday times to draw up the hatches. They send men in—a full army of men—with shovels and scrapers, and they scrape the whole of the stuff down into a very diminished stream, and it comes down solid mud. But when that happens there is, first of all, the blocking of our ponds and the stream below, and, what is a far more serious matter, is that it is absolutely impossible for the villagers below to use the water while this is going on; and, moreover, the cattle in the summer are all turned out in the fields—in the winter some of them would be in the houses, but in the summer they are in the fields—and they cannot drink the water. I have known cases where cattle have gone down to the water and have actually turned back and have been sick after drinking this foul water; others will look at the water and turn away without attempting to drink it.

20231. It is visible?—You can feel it; it is like Egyptian darkness.

20232. *(Mr. Power.)* Does it smell at all?—Smells most foully. This matter which is deposited in the mill dam is a putrefying matter; it is organic, and it goes on putrefying, consequently. The top layers, as Mr. Rawson said, are sometimes valuable river sand, but, when you get down into the horrid polluting, organic matter, and this is put down the stream, it comes down with a low head of water in a most polluted state, and stinks like a sewer.

20233. It replaces the river water for the time being?—It fills this little stream of river water with a highly polluting substance.

20234. There is a large bulk of it in comparison with the water in the stream?—Yes.

20235. *(Chairman.)* That is last year?—Last year was the worst year we have had; it lasted nearly two months.

20236. How was that?—They did it for a week or a fortnight—I think at the mill they were carrying out some repairs—and then after that they did it on Saturday afternoons. The mill stopped off on Saturday, and men went into the dam every Saturday during the summer days; they would work, say, from one or from two up till six.

20237. *(Mr. Power.)* The same dam, do you mean?—The same dam. It had not been sludged out for a long time. I never saw it so clean as it was. It required two months. It takes a long time to get the mud out, unless you do it systematically. The last time I saw it cleaned out systematically I remember as distinctly as possible that it was done with horses and carts. Of course, it is most expensive. Where I could get mud thrown at 3d. a load I paid the other day 5d. I know it is more expensive. I look upon it as part of the working expenses of the mill.

20238. *(Chairman.)* Have you not any remedy at common law?—Yes; you have a remedy, but the difficulty is this: when one mill dam is sludging, the millers below start to sludge, too, or else it would fill up their dams; but while the unfortunate people lower down get the damage done, they cannot identify the actual amount of sludge which is coming down as belonging, we will say, to mill "A"; it belong to "A," "B," and "C."

20239. The remedy at common law is the bringing home to any particular mill the source of the pollution?—You must fix upon one man, and I do not think that a joint action would lie against all three.

20240. Now tell us, do you think the case would be met if some control in regard to dam-sludging were placed in the hands of either Rivers Boards or other authorities that might be arranged?—Yes; if the Government would kindly constitute Rivers Boards, or would compel County Councils to have medical officers of health, I think that something might be done.

20241. Do you think that a Rivers Authority dealing with the watershed would be very valuable all over the country?—Well, I think it would; but, still, I do not see why it is necessary to multiply authorities.

20242. You think the powers could be excercise by the County Council?—I think our Sanitary Committee could deal with the matter if we had a medical officer of health and a proper staff to deal with it, and I do not think that would be any more expensive than constituting a new authority.

20243. Would control, whether placed in the hands of a Rivers Authority or the County Council, of the sludging be sufficient without absolutely prohibiting the passage of the sludge into the stream?—I think that there ought to be prohibition of this scouring, certainly. By scouring I mean to say the sending men to scrape down the sludge.

20244. What I mean is this: If, for instance, the period of flood were selected for the dam sludging, first of all, is it practicable to select such a period, and then would the passage of the sludge at the time when the river was swollen do much harm?—I do not think it would do nearly so much harm. It would be quite a different thing if sludging were simply by pulling up the hatches, as I understand from the last two witnesses is usually done in their districts, and men were not sent into the dam to scrape it down, and if those hatches were simply pulled up, and there was no sludging except during the time of flood in the winter. It should be prohibited altogether in the summer; that is the time we feel it most.

20245. Then the selection of the time for sludging would be one of the elements of control?—Yes.

20246. And the other would be the frequency of the sludging?—Yes.

20247. *(Mr. Power.)* Would it be a grievous burden to put on some millowners, for instance, the obligation to dig out a dam? A few years ago, you say, it was the custom to do that, and now they have given it up; why is that?—Oh! it is simply to save expense, because the law allows them. If the law allows a man to do a

thing which saves him expense he certainly will not go to further expense for the sake of his neighbours.

20248. (*Chairman.*) You think that under the Rivers Pollution Act they have the right not only to impound the water, but to send down the stream the matter which has been brought down the stream?—I think it was an unfortunate construction put on the Act by the Courts above. I do not think it was intended.

20249. Do you think there should be an alteration of the law to meet this case?—Yes.

20250. You really think the case is a serious case?—Oh! yes, a very serious case. These two last witnesses looked upon the rivers as the property of different mill-owners, A, B, C, and D. I look upon them in quite a different light, as public property, in which are interested riparian owners, villagers, and owners of land generally.

20251. Do you wish to make to this Commission any suggestion except those which have been brought out in your answers?—No; I think not, except this: that I am inclined to discriminate between streams in purely country districts and rivers such as are mentioned above, which are always of a polluted character. There is no reason at all why our streams should not be sufficiently good for nearly every purpose. Our own stream would be with a little asistance from the County Council. If we had a medical officer of health and that sort of thing, I think we could make most of our streams pure. But in that case I think the sludging ought to be stopped. I would go so far as this: I would allow the hatches to be drawn at a certain time of the year, but I would not allow any sending of men into the dams and scouring them down—raking down the sludge. When the mill dam required to be emptied, then I think the hatches might be drawn, and the sludge dug out and carted away. I think there would be no harm done in that, and if there was any special case where the sludge could not be dug out and carted away, then I think special leave ought to be given.

20252. There is just one other point I would like to ask you, and that is: There are a certain number of streams with what one might call derelict weirs, are there not?—Yes. *Mr. A. F. Somerville.* 8 Dec. 1904.

20253. Do you think that some power should be given to some authority either Rivers Authority or County Council, to deal with derelict weirs?—Certainly. I think that is most important. I think that there should be power given to Rivers Boards or some authority like that to remove them. I think that is a very important matter, because there is no doubt about it that the freer the stream is from weirs the more purification takes place.

20254. (*Mr. Stafford.*) It is only during the sludging, I understand, that the nuisance arises?—I will not say that. I say the serious danger arises at that time. We suffer a good deal at other times. Every Saturday night the miller draws his hatch, and a certain amount comes down, but the pollution is not at all of the same villainous character as it is when it is done by scouring out the pond.

20255. But the chief nuisance apparently arises at the time of the sludging, which is about once a year?—Yes, and generally when the water is so low: that is my point.

20256. Would not the cost of removing all this sludge by hand, or rather by carting, be very great?—Oh! no I did it myself last year. I removed a great deal from the ponds in front of my house, and I forget exactly what it cost, but it certainly paid for expenses for spreading on the land.

20257. It paid for its expenses?—Yes; of course. I know I spent £38, and I forget exactly how many yards I removed for that. That would clear a good many small mill dams.

20258. Thank you?—I am much obliged to you for allowing me to give this evidence before you.

20259. We are very pleased to have your views.

SEVENTY-FIRST DAY.

Friday, December 9th, 1904.

PRESENT:

Colonel T. W. Harding, J.P., D.L., in the chair. | Major-General Constantine Phipps Carey, C.B., R.E
Mr. W. H. Power, C.B., F.R.S. |

Mr. F. J. Willis, *Secretary.*

ALSO PRESENT:

Dr. A. C. Houston. | Dr. George McGowan.

Mr. R. A. Tatton, recalled; and further Examined.

20260. (*Chairman.*) Mr. Tatton, you are the Chief Inspector of the Mersey and Irwell Joint Committee?—I am.

20261. And on previous occasions you have given us valuable evidence; and to-day you have been good enough to come in order to give us the benefit of your experience in regard to the evils connected with the sludging of mill dams?—Yes.

20262. Now, we had certain evidence yesterday which tended to show, on the part of the persons holding or using the mill dams, that the evils of discharging accumulated suspended matters, which had been brought down by an unpolluted stream, were scarcely appreciable, and that it would be wrong to call upon owners of mill dams to go to great expense to prevent evils which they considered were unappreciable. Now, will you be good enough to give us your opinion in regard to mill dams in your district situated on unpolluted and polluted streams, and tell us whether you think that the evils are real evils, and then give us your opinion as to how those evils might be removed without prohibitive expense to the owners of the dams?—Would it be convenient, Sir, if I read my evidence in the first instance? *Mr. R. A. Tatton.* 9 Dec. 1904.

20263. Yes, you can read any part of it you like, Mr. Tatton, or give us briefly in your own words a summary?—I have divided the sludging cases which we have had in the Mersey and Irwell under two general heads, and we have in the first place the sludging of mill dams; and in the second place the sludging of tanks, precipitation tanks, which have been used by the manufacturers for precipitating their trade effluent. I take it that what you require is especially the sludging of mill dams.

20264. That, in the first instance, is the point upon which we want your opinion?—The waters of the rivers in Lancashire and Cheshire are very largely used for power purposes, and in order to obtain the head to work the turbine or water wheel, as the case may be, dams are constructed across the stream, and the water is either held up in the bed of the stream itself, or is conducted from these dams to a reservoir made, closely adjoining the river. In course of time, these mill dams get silted up by solid matter which is brought down in suspen-

Mr. R. A. Tatton.
9 Dec. 1901.

sion, and owing to the velocity of the stream being reduced, settles in the mill dams. This sludge contains organic matter, I may say, invariably, and is apt to be offensive in the summer; and mill dams, therefore, require cleaning out—at any rate they require the top water being let off—in addition to the necessity which arises of emptying the solid matter out, in order to retain their holding capacity of water. If the sludge is too solid to flow forward by opening the sluices it has been a common practice to send men in with scrapers and rakes and so on, to urge the solid matter forward into the stream. I should say the ordinary practice is first of all to open a sluice to draw off the top water and then to send men in with scrapers and so on to push the sludge forward into the bed of the stream, into the old bed of the stream, through which the stream is flowing when the sluice is opened: the stream then carries the sludge forward into the river down below. It causes very serious pollution, as, of course, the accumulation of probably, it may be, weeks or months or years, which has been settling in the sludge, is sent down in a very short time.

20265. Would you apply the expression very serious in connection with the evils produced from the settlement of matter from an unpolluted stream?—Of course, from an unpolluted stream it is so in a less degree.

20266. You think there is still material pollution?—Yes, there is material pollution. For instance, if it were a fishing river, it is sufficient to smother fish.

20267. Well, you would say it would smother fish. Have you had experience of fish having been smothered under such conditions?—Yes, I have. We had a case; it was not an absolutely unpolluted stream; perhaps I am wrong in saying that, but it was a case where the sluice was opened, and it was a fishing river below, and I had great complaints on two occasions about the fish having been smothered, killed by it.

20268. *(Mr. Power.)* It was detrimental to the fish through the suspended matter, I suppose; not through the sewage or noxious matter that had been in the water?—No.

20269. Would it smell at all on a pure stream?—Yes, it does distinctly; yes; but the fish are not poisoned; they are smothered; it is not from chemicals.

20270. *(Chairman.)* It is mechanical action on the gills, is it?—I suppose that is it, a clogging of the gills.

20271. *(Mr. Power.)* Do people below such a mill dam as that we are speaking of now on an unpolluted stream, complain of disadvantages which arise from sludging?—Yes.

20272. Apart from damage to fish, do they say it is a nuisance or an annoyance or a trouble to them?—Oh, yes, certainly they do. On all streams you get a considerable accummulation; if the water is held up, we will say, for years you get a lot of black mud settling on the banks.

20273. You get leaves and vegetable matter?—You get decaying vegetable matter.

20274. *(Chairman.)* In the case of dams and unpolluted streams what do you find to be the effect of holding back the waters and then at long intervals sludging the dams?—The effect then is to cause an accumulation of this sludge on the banks of the stream, banks and bed of the stream, which is a great nuisance when the water has gone down again. That is one drawback; and, again, if the manufacturers use the water below it is a great hardship upon them.

20275. Does any smell arise under such conditions?—Yes, it does when a dam has been sludged.

20276. Then it may be considered that a dam placed on a polluted stream like that is fulfilling, as it were, the first process of sewage treatment?—That is so, to some extent.

20277. Settlement of suspended matter?—Settlement of suspended matter, yes.

20278. If such suspended matter were not let into the stream at all, but were removed on the land, it would have in itself a valuable effect upon the condition of the stream?—Certainly; it intercepts that amount of solid matter.

20279. But the good which has been partly produced by the settlement in these reservoirs or dams is wholly lost by the return to the river of these matters in a putrefying condition?—It is wholly lost, yes; in fact it is much outweighed by the concentrated pollution, I would say.

20280. Then what do you think would be the remedy in the two cases of dams on unpoluted and dams on polluted streams. I suppose in the case of dams on unpolluted streams you would scarcely think it necessary, would you, to insist that the sludge, largely mineral probably, in the dams should be removed on to the land; would you consider that necessary?—Yes, I should say so; I think it ought to be.

20281-2. Mainly on the ground that this mineral matter would deposit in banks on the stream?—Yes, and cause trouble below to riparian owners.

20283. You would not consider that the regulation of the outflow from such dams would suffice, that there should be some regulations, for instance, that the dams should only be emptied at times of flood, not in the summer time or at holiday times, or at times when that addition of suspended matter to the stream would not cause inconvenience to the manufacturers below; you do not think that would meet the case for unpolluted streams?—I am not suggesting that a mill-owner should be debarred from opening his sluice; that I should accept certainly; he has a right to open his sluice, and any solid matter that goes forward through the opening in that sluice must be received below; you cannot prevent that.

20284. *(Mr. Power.)* He must open it in time of flood, must he not?—He must open it in time of flood; well, he may do so; in some cases they must do so.

20285. To make it safe?—To make it safe, yes; that is to say, if any solid matters is taken forward by the water, in the natural way by the flood, that is so much to his benefit. I do not think that you can prevent that. If you do it means that the mill dam may become a serious nuisance.

20286. *(Chairman.)* Then in the case of dams on unpolluted streams, you are of opinion that the law should be modified so as to compel deposit in those dams to be removed on to land and not to be allowed to be pushed forward into the stream?—I think so. The owner of the dam, whether on a polluted or an unpolluted stream, is damming for his profit, and he gets the advantage of it. I think, therefore, he ought also to accept the liabilities which that dam entails, and not to become a nuisance to his neighbours below.

20287. If that is your view in regard to dams on unpolluted streams, clearly it is also your opinion, to a much stronger extent, on polluted streams?—Yes, that is so.

20288. How would it be possible for any arrangement to be come to between manufacturers and local authorities to utilise these mill dams as a first process treatment of those waters in cases where the dry weather flow consists practically of the flow from the sewage works and trade effluents; would it not be possible to call upon each local authority to contribute towards the expense of removing the matters?—To remove the mill dam, do you mean?

20289. *(Mr. Power.)* To remove the contents of a mill dam?—Oh! to remove the contents. I beg your pardon. Well, I should object really to their being used as sewage treatment in the first instance.

20290. *(Chairman.)* Well, but as a matter of fact the deposit of these matters in the mill dam, although an accidental result, is in itself a useful result, if the deposited matters could be removed wholly from the river on to land?—They are returned to the river afterwards; any good produced by the settlement is lost.

20291. *(Mr Power.)* It is sedimentation for the time being?—Yes, quite so.

20292. *(Chairman.)* Therefore, are not the whole population on the banks of the stream interested in its being done, and ought they not to some extent contribute; I merely suggest that with the idea of getting your view upon it?—I do not think you could do that any more than you could ask a community to clean out a manufacturer's tank in which he treats his trade waste.

20293. Then your view is that local authorities ought not to be called upon to pay towards the expense of removing matter out of dams in polluted streams, however valuable such removal might be to the whole population on the banks?—No, I think not; the dams are made by private individuals; they are private property.

20294. Well, we have had your opinion, Mr. Tatton, as to the evils; now, the next point is as to the means of preventing these evils. I think you hold the view, do you not, that suspended matter that has been deposited and has become sludge, and is urged forward into the stream by means of scrapers, or streaming of the water, causes the person who does this to be liable to an offence under Part I. of the Rivers Pollution Prevention Act?—Yes, that is so.

20295. That is your view, is it not?—Under the Mersey and Irwell Act, not the Rivers Pollution Prevention Act of 1876.

20296. The Mersey and Irwell Act is somewhat stronger?—It is somewhat stronger.

20297. But you know that under Part I. of the Rivers Pollution Prevention Act that that is an offence?—No; I do not say that; we have not worked under the 1876 Act, which is the one you alluded to, but under the Mersey and Irwell Act. My experience has been that the Mersey and Irwell Joint Committee Act of 1892 is distinctly stronger. In that Act we have the word "sludge" inserted.

20298. But in the paper you were good enough to send on to us I see this passage:—"Once the suspended matter has been deposited it becomes sludge, and it matters not whether the offender urges it forward into the stream by means of scrapers or by means of a stream of water, he is liable for the offence under Part I. of the Act, and he has no appeal to the Local Government Board." ?—Under Part I. of the Mersey and Irwell Joint Committee Act.

20299. It is Part I. of the Mersey and Irwell Act?—Yes.

20300. I see; under what clause of that Act do you consider that he is committing an offence when he does this?—Under Part I. Clause 2.

20301. Would you read the clause if you have it before you?—I am sorry to say I have not the Act.

20302. Clause 2?—Part I. Clause 2. I have not got a copy of the Act.

20303. On the paper which you have placed before us there is a clause from the Mersey and Irwell Joint Committee Act, 1892; is that it?—That is the saving clause.

20304. The Saving Clause; it is not the clause specifying the offences?—No.

20305. Well, we may, perhaps, come upon it presently. Then I may take it generally in your own area you have had no difficulty in dealing with the evils of dam-sludging; you have obtained convictions in all of these cases where dams were on polluted streams?—Yes, that is so; we have had seven cases, and we have obtained convictions in all cases.

20306. (*Mr. Power.*) There has not been an appeal in any instance?—No, Sir; not in any instance.

20307. (*Major-General Carey.*) And where the water was polluted by the owner after receiving it into the mill dam?—No, it was polluted before it arrived in the mill dam; the owner then sludged out his solid matter into the stream, and we prosecuted him for sludging out the solid matter.

20308. (*Chairman.*) Is Part I. Clause 2 of the Mersey and Irwell Joint Committee Act, in your opinion, a stronger clause than the corresponding clause in the Rivers Pollution Prevention Act, 1876?—Yes; I think it is. We have the word "sludge" in that Act; you will see it is introduced; it was introduced for the specific purpose.

20309. Is that the main difference between the two Acts, that in your Act the words, "or any sludge," are introduced?—That is the main difference. I should define sludge as the result of the deposit of suspended matter.

20310. Then in your Act you have a Saving Clause to this effect, that persons shall not be considered to be committing an offence for putting into such river or stream any sand or gravel or other natural deposit which shall flow there, or have been deposited by the current of any such river or stream?—Yes, that is so.

20311. That is the Saving Clause?—That is the Saving Clause.

20312. And am I right in taking it that, in your opinion, that applies merely to unpolluted streams; to the deposit brought down by unpolluted streams?—Yes, certainly.

20313. Then in cases where you have prosecuted you have obviously not considered that that clause permitted of the sludging of dams on polluted streams?—No; none of the cases that we have taken into Court that we have prosecuted come within that Saving Clause; in no case has that been maintained.

20314. We are anxious to find out whether the condition of the law as it stands is sufficient to prevent the evils connected with the sludging of mill dams on polluted streams. You seem to be under the impression that the clauses of your own Act are so?—Well, so far we have found them; none of our cases have been appealed against; they have all been fought.

20315. Yours is of limited application?—Yes.

20316. Under the general law you think the powers are insufficient?—Yes.

20317. Under the general law you think you want something stronger than this Sub-Section 3; you do not think it should be exempted?—No, I do not think it should; we should want something stronger than that in the case of unpolluted streams.

20318. (*Major-General Carey.*) Do you consider that the sludge should be removed from mill dams under any circumstances, whether the water coming down from the mill dam is polluted or whether it is not—that the sludge should be removed by the manufacturer, and should not be passed into the river?—Yes, I think it should. I think the proper way in all cases is first to reduce the water in the mill dam, and then to remove the sludge on to ground outside the mill dam.

20319. Would manufacturers always have the means of doing it—the means of removing that sludge?—I know of no cases where there would be any practical difficulty in the way of that being done. Of course, it is a matter of cost; it is cheaper for them to send the whole thing down, to sludge the dam only.

20320. Yes, of course; the argument, as I understand it, of the manufacturer is that he receives the water in a certain state, and he discharges the water into the stream in the same state?—Yes.

20321. It has not become worse except by the deposit of the sludge; which has been going on for a considerable length of time; that he is not responsible for the state of the water which he receives in a polluted state; he delivers it back into the stream in the same condition?—Well, he does not deliver it back in the same condition; he accumulates all this filth that is in the stream, all this suspended matter, which perhaps in itself would not cause a serious nuisance if it were allowed to flow past his works in the natural way, and discharges the whole of the accumulation in a short time, making the condition of things very much worse down below, no doubt, for a limited period, but still the evil is greater for that period.

20322. The intervals at which he discharges sludge may be very considerable?—Oh, yes, they may.

20323. Sometimes a year or two years?—Yes, they may.

20324. (*Mr. Power.*) As to the construction of these mill dams—they are commonly made artificially watertight, I suppose; are they concrete, or merely puddled, or what?—Yes, very fairly watertight as a rule.

20325. But they do not concrete them for facilities of emptying them, do they?—As a rule they have a sluice which would have concrete abutments; in some cases they are very roughly made; they only hold the water up in some cases, perhaps four or five feet deep, so that you have not a great weight of water against them.

20326. In other parts of the country there seem to be various methods of dealing with such dams. In some they run them dry—when they have time, I suppose, at their disposal—and wheel out the contents on barrows; and in some, I have seen it myself, they have a flat-bottomed punt with a pole and a scoop at the end of the windlass rope, and thus they dredge out sludge without interfering with the operations of the mill or the pond. Are any of these methods practised in the district within your jurisdiction, or has the sole method in the course of time come to be this sludging process that you have described—driving everything into the stream?—I should say that these systems that you have mentioned are not practised at all; I have seen that done which you have described.

22327. Are those other methods falling into desuetude, do you think, in preference for the method that

Mr. R. A. Tatton.

9 Dec. 1904.

you spoke of?—I think they prefer the method I have described if they are allowed to use it.

20328. A suggestion has been made that some of these people imagine that under the Rivers Pollution Act they have some sort of licence to do this; is there any such impression abroad, do you think, in your district?—Are you alluding to the 1876 Act?

20329. License to get rid of this accumulation in their dam provided they send down nothing more than comes to them?—Well, I cannot say that, sir; I have not worked under that Act at all on the Mersey and Irwell watershed.

20330. (*Chairman.*) You probably are acquainted with the case of the Ribble Joint Committee *v.* Halliwell; does not that bear out the case Mr. Power is speaking about?—Yes; I only know from reading about it; yes, I think it does there; on the Ribble they are working under the 1876 Act; they have not got the extra powers which we have under the Mersey and Irwell Act.

20331. Then may we take it that, in consequence of the successful prosecutions which you have carried out under your Act, owners of dams in your district generally remove all matters from dams on to land?—I think generally they do.

20332. And you think the expense of doing so is not a prohibitive expense; it is found in your district to be practicable to do this?—Yes, it is.

20333. In certain cases you can see it would be somewhat difficult to remove these matters; in a valley with very steep sides, where a road was not available, close to the dam, and so forth. Do you think in many cases, especially with regard to dams on unpolluted waters, that the control of the discharge by the Rivers Board or other authority would be useful control; I mean in regard to times of discharge, and the length of period of stagnation, and so on?—It would be very difficult to work that, I am afraid.

20334. It has been suggested that, for instance, the discharge should not be allowed in dry summer weather?—Yes.

20335. That people should be compelled to discharge at times when the flow in that stream was sufficient to carry matters rapidly forward, and at times when the discharge would not inconvenience manufacturers lower down and so on it has been suggested to us that such control placed in the hands of a supervising authority would in these matters be very useful. Do you think that it would, or is it your opinion that in no case should discharge be permitted?—I do not think it should be permitted; it is very difficult to say; at certain times you may discharge your mill dam and at certain times you may not; it is very hard to regulate them; the inclination of the manufacturer is to do it when he wants to do it.

20336. You think that that kind of control would not be of much value?—I think it would be very difficult to work.

20337. And that the really right thing to do is to prevent the discharge altogether?—I think that is so, yes.

20338. Very well, we might pass on now to another point upon which we are anxious to have your views, and that is as to the possibility of dividing the streams or watersheds into zones, and having standards of purification applicable to each. We felt that you have had a large experience in the administration in your district, and that you have at present, I believe, a sort of provisional standard upon which you act?—Yes, we have.

20339. And therefore your experience is sure to be a very valuable one?—I am of opinion that the standard should be uniform over the whole watershed or administrative area, both from an administrative and also from an equitable point of view. As regards the administrative aspect, given that the standard effluent of the future will be an effluent that, apart from the question of suspended matter, will not decompose in itself, and will not cause any trouble if discharged into an unpolluted stream or into its own stream.

20340. (*Mr. Power.*) That is the minimum of requirement?—That is the minimum of requirement; I think we must have that.

20341. Have you any drinking water streams in your district; streams that are used as a source of water supply?—No.

20342. (*Chairman.*) Would you be disposed to modify that standard in such case?—To make them easier?

20343. (*Mr. Power*). No, a higher minimum ——

20344. (*Chairman.*) Supposing you were discharging into a stream that was used for drinking purposes?—It would certainly have to conform to that standard if it went into a drinking water supply.

20345. (*Mr. Power.*) Would you not have some requirements superadded?—Yes, I think you certainly would require to have something more than that.

20346. You are not concerned with that consideration in your district?—No, we are not; our rivers are too bad.

20347. And therefore your standard has been, so far, with a view to bring people into line?—Yes, it has.

20348. (*Chairman.*) Then where would be the evils in your opinion of having a varying standard applying to different parts of the river or watershed?—Well, having a variable standard would mean that the large towns, which are usually on the lower reaches of the river, would have easier requirements than the smaller towns higher up.

20349. (*Mr. Power.*) Something below what you have just told us?—Something below what I have just told you; that is, I presume, what the suggestion would be, that if you had a variable standard you should have a lower standard for the lower reaches of the river where there is a large volume.

20350. Of course, the Commissioners have made no standard yet, but I think many of us would not like to go behind the standard that it will not allow a putrescible effluent?—That is a very important point.

20351. I speak subject to Colonel Harding's opinion; I think certain of us have a tendency that way, at any rate?—Yes.

20352. Of course, the towns lower on the river, if they had a larger amount than those above of organic matter left in their effluent, might, so long as their effluent was non-putrescent, be allowed that larger amount of organic matter, but I should think the condition of non-putrescibility could not be relaxed?—Yes.

20353. (*Chairman.*) You do not think that the question of relative dilution could be considered as well as the question of relative pollution of the stream itself?—No, I do not think it should. I think that in the first place as regards equity it is fair to expect the large towns to treat their sewage as efficiently as the small towns. What it comes to is this, that the saving in getting a good effluent, in getting an effluent which I should pass as an efficient one; the difference between that point and a lower standard does not necessarily entail a very great expense. In any case you would have the sewers and the outfall works, and probably single contact to pay for, but in order to bring your effluent up to our standard it would merely mean extra filtration, which is a small proportion of the total cost your works have required.

20354. Then we quite understand, now, Mr. Tatton, that in your view variable standards of the kind suggested would not be advisable?—No, I think not.

20355. And that you think an effluent which in itself would be non-putrefactive is essential in all cases?—I think that is essential in all cases.

20356. Well, now, passing on to the question of storm waters, Mr. Tatton, you have been good enough to place before us a valuable report bearing on the storm waters of Stockport, Macclesfield, and Rochdale, and given us the benefit of certain notes and analyses which have been made in regard to those. Now, it is difficult perhaps to gather—I have not had the opportunity of spending much time over this report as yet—it is difficult to get from it any information as to the number of dilutions of sewage which in your opinion should be treated. It was difficult I see to get even accurate information at these various places of what amount was being treated and what amount passed away, and no doubt as yet there is very indefinite and incomplete information in regard to storm waters either as to their volume or as to their composition, but you have in these tables contributed a good deal of information towards that, and we are getting information in other directions. But I gather generally that the amount of storm waters which are being treated, which are here referred to, do not rise above three or four volumes of the dry weather flow?—That is so.

20357. In your district have you many cases of authorities, especially the more important authorities,

that are dealing with the six volumes of the dry weather flow, which we understand the Local Government Board require to be treated?—No, I have very few.

20358. (*Mr. Power.*) Does that mean that their overflows come into operation before the three, four, or five volumes are reached?—Yes, that is to say in the case of Macclesfield, which I have quoted here, the storm overflow comes into operation when the storm water was equalling two and a half times only the dry weather flow. Of course, that did not mean that we got no more sewage down to the outfall works; it still continued to flow down to the outfall works.

20359. But some passed away when it flowed down at that rate?—A certain proportion passed away at that time.

20360. (*Major-Gen. Carey*). Over two and a half times the weather flow?—Over two and a half times the dry weather flow.

20361. That passed into the river?—A portion of it, which we are not able to gauge, passed into the river, and the remainder passed forward into the outfall works.

20362. (*Mr. Power.*) In a case like that, Mr. Tatton, however stringent your standard might be for what passed through the whole "treatment" process a considerable amount would be allowed to go into the stream which should not go there?—Oh, yes, that is so, and the trouble is that storm overflows do a great proportion of the harm in the summer time; if you have a sudden thunderstorm in a hilly district, the water will flow down the sewers with great rapidity, and even if you fix your overflows, say, at six times the dry weather flow, it may go over these overflows in very large volumes into the river at a time when the river is low and cannot deal with it—cannot carry it forward.

20363. This might occur in a fraction of the 24 hours?—In a fraction of the 24 hours.

20364. And you think the volume might be very large that so passed over in a short time?—It might be very large indeed.

20365. (*Chairman.*) But evidently you think that storm waters beyond six times the dry weather flow are still polluting?—Oh, there is no doubt about that.

20366. And do you think that, say, 10 or 20 times diluted, there would still be pollution carried to the stream?—It depends on the place entirely; you must take each place on its own merits. If you have a hilly district you want your overflows at a higher level than in a flat district, because the sewage finds its way down to these overflows much quicker than it does in a flat district; it rushes down from the overflow into the river; whereas if the district is fairly flat it takes a considerable time and is more equalised, and you get more sewage down to the outfall works and less over the storm overflows.

20367. (*Mr. Power.*) In the speedy operation of the storm-overflow you would get the first washings of the storm, which are perhaps the most objectionable?—That is exactly the trouble; they are most objectionable.

20368. Have you made any attempt in your area to regulate the point at which this, that, and the other overflow of a town sewer should come into operation?—What we do is not to suggest a volume, but if we find the overflow is apt to offend periodically we make complaints about that overflow and have the sill raised, and I think that is really the way to tackle the difficulty.

20369. (*Major-General Carey.*) To raise the sill?—To raise the overflows until you find that they do not come into operation when the stream is low. Of course, we admit that at times of very heavy rain you must have on our rivers which are not used for drinking purposes—there must be some overflow.

20370. Is the dry weather flow calculated on the average of the 24 hours, or on the maximum in a day?—It is on the maximum; the average maximum flow—that is to say, taking each day, you take the maximum flow of each day, and you take the average of these days, and dilution is calculated on that maximum, on that average maximum; that is to say that it would be considerably more than the average dry weather flow of, we will say, six o'clock in the morning; the maximum flow is probably about 12 o'clock in the day; two and a half times dilution at 12 o'clock would mean very many more dilutions at six o'clock. What I mean is this—that supposing your overflow is at a fixed level and it comes into operation, it may be when the sewage is diluted up to a volume of two and a half times at midday, it would not come into operation when that sewage was diluted up to two and a half times at six o'clock in the morning.

20371. No, there would be less volume passing through the sewer?—There would be less volume passing through the sewer, yes.

20372. You take the average of the maximum?—Yes.

20373. (*Mr. Power.*) The average of the highest dry weather flow at noon.

20374. (*Major-General Carey.*) How do you get the average?—We take it over a period of six weeks and during dry weather in the summer.

20375. Then, I notice, to take one of these places, mentioned in the Report which you have made to the Commissioners on sewage flows, that, in 1902, the flow reached six times the dry weather flow—five times, four times, four times, four times, six times, five times, four times, seven times, six times, five times, four times; so that there are a large number of cases where it has exceeded three times?—Yes.

20376. At least, in which it has exceeded the three times?—Yes, but I must explain that. In that table the rates are worked out on the dry weather rate of that particular hour. For instance, if you take Table A1—take March 22nd, 1902—the time of the storm was between 12.20 and 1.40, that is 1 hour 20 minutes; the rates of dilution were six times for 20 minutes, five times for 45 minutes, and four times for one hour. That is the actual time the storm took place.

20377. Yes?—That is the night flow, you see; and, therefore, those dilutions would very soon be reached, because they are taken for the particular dry weather rate at that hour.

20378. It would be the sewage running at its minimum then, between 12.20 and 1.40 a.m.?—Yes, it would be.

20379. On the 25th, 1 o'clock a.m.—that would be the same thing, "early morning eight times"?—That is the same thing.

20380. (*Mr. Power.*) Given a minimum standard that the effluent should attain to, I rather gather that you are disposed to consider that it may be necessary to fix by authority the level at which overflow at the weirs on sewers should take place for each town; and not only at the outfall works, but on the several sewers of the town according to their gradients?—Yes.

20381. It would have to be done by an authority, which would have regard to the total flow of the river, I suppose, and the amount of purification effected on that part of the sewage subjected to full treatment, as well as to the liability to overflow at the weirs?—Yes, that is so; the whole system should work together. All the overflows should be regulated, whether in the towns or at the outfall works, to conform to whatever the requirements are.

20382. But then, if you have a uniform standard which must be observed, it seems to me you must have separate regulations at each place as regards the overflow weirs, and not only on the outfall sewer, but on a number of sewers; it would amount to that, would it not?—Well, your standard would not refer to the condition of the storm water, but to the volume.

20383. Yes, it would affect the volume that would pass away?—Then it would vary.

20384. If you are dealing with two and a half or three volumes completely at the outfall works, and you have liability through the position in which the weirs are, not only that on the main outfall sewer but on other sewers, that anything beyond this will pass away in greater abundance in the storm when you get six, seven, or eight times that of the dry weather flow for a short time, you may have to put these weirs higher. But would not that mean you would have to apply a general principle in each particular instance in the town?—Yes, that is so.

20385. (*Major-General Carey.*) You would have to rely on the local authority to raise their weirs?—Yes, with inspection. Supposing we found one overflow in the town came into operation before the others, we should then complain to the authority and get that overflow raised. It would have to be done by inspection, but there is no difficulty about that; we do it now to a great extent; we have had a great number of overflows raised that were serious offenders.

Mr. R. A. Totton.

9 Dec. 1904.

20386. Those in which compulsory action has really been taken by the Rivers Board?—Yes, that is so.

20387. (*Chairman.*) I have one or two more questions which I ought to put to you, Mr. Tatton; and one of the most important things we should like to know from you would be your opinion as to the number of dilutions it would be proper to ask the local authorities to treat. I notice in the table you have placed before us that when a volume of dilution has reached four, you have it by the analyst's evidence that such storm waters are really more polluting than the dry weather flow of the sewage?—Yes, that is so.

20388. Therefore, clearly, if the consideration to guide us is to be the number of dilutions which produce so small an amount of pollution that it may be left to the self-purification action of the stream to get rid of it, we should have to fix the standard at a great many volumes of dilution, should we not?—You would in certain cases, no doubt.

20389. There might be exceptional cases where it might be more or less, but, speaking generally, you would have to fix the number of dilutions to be treated, if that was the only matter you were considering, the proportion of dilution, you would have to fix it very high indeed—10, 20, 30 dilutions, something like that?—I do not think it would be as high as that. But in cases of towns with hilly sides it would undoubtedly be higher; but, of course, it is the rate of flow we are speaking of now; that does not necessarily mean so many volumes to be treated at the outfall works; for instance, supposing you fix your overflows eight times the rate of dry weather flow, it does not mean that you would have eight times the dry weather volume discharged at the outfall works; it might only come up to that eight times say for an hour, and then go down again, and your volume perhaps would not be more than five.

20390. I quite appreciate that; but suppose we were merely to be guided by the question of pollution of streams, should we not necessarily have to fix the number of dilutions before which storm overflows should come into operation at a very high level? Clearly, then, six dilutions would not suffice, because I notice in one of the analyses of the Macclesfield storm water that the oxygen absorbed from storm waters over six times diluted was 37 parts per 100,000. Whereas in the dry weather sewage of Macclesfield it was only 4·35?—Yes.

20391. In settled sewage; and you may take it probably it would be 9 or 10 parts in the absolutely crude sewage?—Yes.

20392. So that really at six dilutions we had here storm waters, which, as measured by the oxygen absorbed, were three times as bad as the dry weather flow of sewage; therefore, clearly six volumes would be insufficient if we are to be guided simply by the idea of preventing the pollution of the stream?—It would.

20393. Then is it in your opinion practicable to call upon any authority to deal with such a number of dilutions as should prevent pollution of the stream?—I should not like to say that. I think it would not be a hardship to call upon authorities to treat six volumes.

20394. It would not be a hardship to call upon them to treat something more than six times?—I do not think you would require to treat many more than six times.

20395. You think it is impracticable for them to treat more than six times?—Well, it is all a matter of cost obviously. In some cases it may entail extra sewers.

20396. What I want to get at, Mr. Tatton, is this; must we be guided by that which is financially practicable, or must we be guided by the question of the pollutions of the stream. It would seem to me from the data which you have placed before us that the number of dilutions would have to be very great before you would allow storm waters to come into operation, if you were to be guided alone by the question of pollution of the stream?—Yes, I think they would.

20397. And therefore you would probably consider a more or less empirical limit, the limit of what is financially practicable?—Yes, clearly.

20398. Is that your view; I am very anxious to get your view?—It must be fixed so to some extent.

20399. Do you think we must be guided by what is financially practicable in this case, and that it is not possible to reach the treatment of so large a number of times as would really stop any serious pollution of the streams?—I think that where a town is situated so that its storm water does seriously pollute the stream it is right to call upon that town to increase its outfall sewers if necessary, because that is where the expense would come in in order to prevent that pollution.

20400 But you must be guided, must you not, by what is financially possible?—Yes, clearly we must.

20401. What is, then, your opinion of the provisional regulation which I understand is applied by the Local Government Board at the present time; it, I understand, requires that six volumes of the dry weather flow should be treated; some of them fully and some of them partially; do you think that that is as far as is financially practicable for local authorities to-day, and do you think it is practicable for them to go so far?—I think, on the whole, that that is a very fair requirement to ask them at the present time. I think in certain cases where they do seriously pollute even with that volume taken down to the outfall works that they should be required to go to extra cost in consequence.

20402. You mean it is reasonable not to ask them to deal with more than six volumes in any case?—I think it may be in some cases. It is very hard to lay down a hard and fast rule; as I have said, I think you must take each case on its own merits. If the town seriously pollutes, periodically, in summer, a clean river, we will say by storm water, it seems to me fair then that you should ask that town to go to more expense than another town in which the conditions are different in order to prevent pollution.

20403. Then would you in such cases ask them to deal with more than six times?—You might.

20404. How many more would it be practicable to deal with?—I cannot say that at all.

20405. As a fact have you any considerable authority in your district which does deal with six?—No, I have not.

20406. Have you any which is proposing to deal with six?—Manchester is proposing to deal with six.

20407. (*Major-Gen. Carey.*) Not to fully treat six volumes, but I suppose to treat a certain proportion of six volumes,—say, three volumes—as sewage; and the rest to be treated in a necessary reservoir?—Not effectually; no, sir; I do not say that; what you want to do chiefly is to remove the suspended matter from the storm water.

20408. Yes; that is the trouble. It is the suspended matter which settles on the banks of the streams and causes a nuisance afterwards.

20409. (*Mr. Power.*) Is not one of your points this; that it is not so much the six times the volume of the dry weather flow you are considering, but you think that in certain times of storm, when sewage is coming down at the rate of above six times the dry weather flow, something must pass away into the river that should not go there, and that accordingly you would prefer that the sill of the overflow was put higher in certain instances; that it should not overflow until, say, a rate of 12 times the dry weather flow was reached, you being in expectation that at the end of the 24 hours you would not have got more than six times the volume of the dry weather flow delivered to the works?—Oh, certainly, that is so.

20410. You would not allow the overflow to take place so early as at six times the rate of dry weather flow on the expectation of that, although raising the sill would entail more coming down to the works at one time of the day. You would not by the time the 24 hours had expired have had more than the six times flow to deal with at the outfall works?—Quite so. You might have a considerably larger rate of flow than six volumes.

20411. Yes, at the end of the day?—A total volume of not more than three or four.

20412. I think that was your point that you think more passed into the river in time of storm than you think right should go?—Yes.

20413. A higher overflow weir does not necessarily entail the authority dealing with six or seven times the dry weather flow at the outfall works?—No, it is more a question of sewers; it entails carrying more forward to the outfall works.

20414. That rather leads back to what I was asking you before. Does that not mean that these overflows must be fixed by authority in the particular instances?—Yes, by a rivers authority.

20415. As the Chairman was suggesting, they may as a result have to treat more than six times the dry weather flow?—At the rate.

20416. It might work out in over six volumes, but in a good many instances you do not think it would?—No.

20417. They would have, of course, to accommodate during storm, a larger amount than the sewers will accommodate at present?—Quite so, but the actual volume which they would have to treat would not necessarily be more than six volumes of the dry weather flow for the day.

20418. The volumes they would have to treat in the course of a month would not exceed six times the dry weather flow for a month we will say?—Oh, no, certainly not; nothing like it.

20419. It is the storm water that you are most uneasy about from the rivers point of view?—Yes, that is so, it causes most serious trouble in the summer.

20420. (*Chairman.*) In most cases the sewers are not large enough to carry anything like six to twelve volumes of the sewage, are they?

20421. (*Mr. Power.*) It would mean reconstructing the system of sewers; the outfall sewer at any rate?—It would do in some cases, but I think at the present moment the Local Government Board insists on their treating that.

20422. Extra tanks for receiving extra storm sewage?—Yes; a very good way of dealing with it.

20423. (*Chairman.*) In Manchester they are proposing to deal with six volumes; are the main sewers at Manchester at the present time capable of dealing with six volumes?—No, they are not.

20424. Therefore it would mean additional sewers?—Yes.

20425. Greater additional expense?—Yes.

20426. Is Manchester prepared to go to that expense?—They are looking to it; we are complaining to them of their storm overflows.

20427. (*Mr. Power.*) They revised their system of storm overflows five or six years ago?—Yes; they have many overflows in the town, which come into operation, much below that six times.

20428. (*Chairman.*) Although, as Mr. Power pointed out just now, the storm waters may only come down for a limited period, still if you are, during such limited period, effectively to deal with those storm waters the plant at the sewage works must be adequate?—Yes, that is so.

20429. Therefore at times when your overflow is not passing you would have a plant greatly in excess of what is required during dry weather?—That is inevitable; you always have that at works.

20430. Clearly, to do it it means for a short period it might be desirable to treat, as Mr. Power suggested, above six, say, up to 12 volumes. You could not do it unless you had first of all sewers large enough to bring such volumes to the works; and, secondly, a plant large enough to deal even for a short time with these volumes?—That is so.

20431. Therefore, we come to this, what is financially practicable to be done; and do you think that the existing provisional regulations in regard to the question of dilutions are fair; should they be exceeded; should they be diminished, or what?—Six times the volume.

20432. Yes.

20433. (*Mr. Power.*) Do you think that if the overflows were universally fixed at six times the rate of dry weather flow, which they are not now, a very great deal might be gained, and that taking it on the whole what went over would be negligible, or do you think some further consideration needs to be given to this question?—In certain cases six times would not be sufficient.

20434. At present I suppose very few towns in your district have a rigid standard of six; they are below, are they not, very generally?—Yes, they are below it very generally.

20435. Supposing universally throughout your watershed no overflow were allowed until a rate of six times the dry weather flow was reached, would not a very great deal be gained, do you think?—A great deal no doubt would be gained.

20436. But you do not think sufficient?—But we would still have pollution in summer in thunderstorms.

20437. Heavy downpours?—Yes, principally in Macclesfield.

20438. You would like these heavy downpours impounded and dealt with before going direct into the stream?—Yes.

20439. (*Chairman.*) Referring once more to your opinion that six dilutions which are now required to be treated are a fair quantity to expect the authority to deal with, why do you think that six rather than five or seven would form a proper basis?—You must take something as a basis to work upon. I do not say that six times will do in all cases at all; I think in some cases it might be varied.

20440. I understand this is your view, that many times more might still be called pollution?—Yes.

20441. What we are trying to get at now is what in your opinion is financially practicable in your district. I understood you to say that this six times was a fairly practicable thing to require?—I think it is fairly well accepted as practicable in my district.

20442. Would it be practicable to go further and ask for more dilutions to be treated?—In certain cases.

20443. Do you think it would be financially practicable?—It is very difficult to answer that question, because it depends upon the financial condition of the town to a great extent.

20444. The condition of its sewers?—The condition of its sewers; they might have to lay new sewers entirely for it; they might be in great financial difficulties, and could not afford to lay new sewers.

20445. Meantime we may take it as your view that it would be reasonable to ask the local authority to deal with six dilutions, some of them fully and some of them partially?—Yes, I do.

20446. Well, now, as to such partial treatment, I notice that in many of the cases that you have brought before us these storm waters are actually worse, more polluting than the dry weather flow; that is so, is it not; it is also in harmony with our experience elsewhere?—Drs. Houston and McGowan have made the analyses; I am answering on their analyses; I am not a chemist.

20447. Dr. McGowan, may I take it that is so?—(*Dr. McGowan.*) Yes, in some cases.

20448. I will tell you the point that seems to us to be very interesting to get at, is your highly polluted condition more largely due to suspended matter than to dissolved impurities in the case of storm waters?—(*Mr. Tatton.*) That is a very important point which I am not able to answer; that, I take it, is a chemical question.

20449. That is a point which we shall have to ascertain from Dr. McGowan?—I think it is a very important point to ascertain.

20450. If it were found, as appears to me not at all unlikely, that the impurities of storm waters are much more largely in suspension that in solution, then that would point, would it not, to the necessity of the partial treatment of storm waters being directed to the settlement of such suspended matters?—Yes, it would.

20451. Have you generally been able to form an opinion whether the settlement of suspended matters in the storm waters does result in giving you an effluent which is fairly free from dissolved impurities?—I cannot tell you that, but I can say that a comparatively short period of settlement of storm water effects a very great improvement. The suspended matters in storm water seem to precipitate more rapidly than the suspended matters in ordinary sewage, and I have no doubt that it is the suspended matters in storm waters that do cause trouble, because they settle on the banks of the stream.

20452. I am interested in hearing that opinion from you, because it is in harmony with the opinion we have heard from several others who have had practical knowledge of these matters that the suspended matters in storm waters do settle more rapidly than the suspended matter in the dry weather flow?—Yes, that undoubtedly is the case.

20453. Then you consider that point is one which it would be very important for us to investigate?—Yes.

20454. As to the relation between the suspended and the dissolved impurities in storm waters?—I do.

Mr. R. A. Tatton.

9 Dec. 1904.

20455. (*Mr. Power.*) I suppose you have never seen, in any part of your district, any contrivance adjusted to the storm overflow, something in the nature of a rough filter, so as to pass the early overflow in a storm through some sort of a filter or a strainer, have you?—No, I have not.

20456. Something might be gained, possibly, from an engineering point of view, by putting small filters or strainers on the overflow. Has it been attempted, do you know?—No, it never has, as far as I know. I am afraid the difficulty would be that you would so soon get the filter clogging up.

20457. It would want constant attention; it would probably want renewing, or turning over, after each storm?—Oh, yes; I am afraid the first rush of the storm would block it up.

20458. It would necessarily have to be of small area, because such strainer would probably be in the position where it could not be large?—Yes; however, I have had no experience of it practically.

20459. (*Chairman.*) There is just one other important question I should like to ask you, Mr. Tatton; and that is, when we spoke just now about dealing with six volumes of the dry weather flow, and when you expressed generally an approval of that empirical limit, we should understand, of course, that you would consider that that cannot be a fixed limit applicable everywhere. There must be instances where obviously it must be modified. For instance, in the case where you have sewers bringing down a considerable amount of subsoil water, so that the dry weather flow in those cases is abnormally high, it would in such cases be unfair, would it not, to call upon an authority to deal with six dilutions not only of its domestic sewage, but of this subsoil water? Let me take another case. Cases where you might have in sewers a considerable amount of trade effluents, consisting, say, to some extent of innocuous discoloration; it would perhaps scarcely be fair to require that such trade effluents should be dealt with in six volumes of dilution, in the same way as the domestic sewage. Then take yet another case, where one authority had an abounding water supply and another authority had an insufficient water supply; you might have a consumption of water in the one case of 25 gallons and in the other of 50; it would perhaps scarcely be fair to call upon the authority which had an abounding water supply to deal with six times the dry weather flow in the same way as you call upon the other authority with the inadequate water supply also to deal with six volumes. Does not that lead us, therefore, to this point, that it might be necessary in fixing the volume which is to be multiplied by six to take so many gallons a head as the basis? What do you think about that?——

(*Major-General Carey.*) I think that is really shown in the Local Government Board provisional rules; it is six times the dry weather flow of sewage.

(*Chairman.*) Based on volume per head.

(*Major-General Carey.*) Of sewage proper, the trade water being absolutely separated; you do not multiply the total by six.

(*Chairman.*) Can you tell us what is the basis which they take; is it 25 gallons per head, or what?

(*Major-General Carey.*) The basis is the actual dry weather flow, based very often on their water consumption. The authority are able to state their own dry weather flow.

(*Chairman.*) Is there any allowance made where there is an abundant water supply and where there is a deficient one?

(*Mr. Power.*) I do not think there is.

(*Chairman.*) The point I want Mr. Tatton's opinion on is this. I understand he considers that it is fair to call upon an authority to deal with six times its dry weather flow, but I want to know whether he thinks the volume of the dry weather flow should be any volume arrived at by multiplying the number of the population by a certain reasonable figure of water supply which should be constant in all cases?—I should be inclined not to make a hard and fast rule, and not to fix it definitely at any amount of dilution; that is to say, that each case should be judged on its own merits; and I should be guided to a great extent by the result of the analyses of the sewage.

(*Mr. Power.*) You take as a basis the strength of the sewage, do you mean?—I mean that supposing you have a very weak sewage with a large amount of subsoil water, if you dilute that down you might possibly—I will not speak from the chemical point of view—arrive at an effluent which would be non-polluting from our point of view.

20460. (*Chairman.*) Then we are to take it that your rule of the six volumes being a reasonable amount requiring to be treated is a general view?—That is it.

20461. And you would modify it and be guided in specific cases by the condition of the sewage itself?—Yes; I should take all the circumstances of the case into consideration, and I should not fix it by statute at six times, and I should not allow it to be an answer to a charge of pollution. If an authority were polluting a stream, although treating six times the volume, I think that they should still be held liable, and that the fact that they are treating six volumes should not be an answer to a charge of pollution.

20462. Then you seem to be in favour of having no fixed rule in regard to the dilutions?—I should only have a professionally fixed rule, the same as we have with our standards. It is only a provisional standard to see how it works; in certain cases we should have to go beyond it.

20463. Mr. Willis calls my attention to this, that it would be very inconvenient to have a constantly varying standard. If an authority proposes to carry out a scheme, and you fix a number of dilutions, and they construct their sewers to suit them, it would be extremely inconvenient if shortly afterwards you raised the number of dilutions to be treated, so I think it is rather important that we should get at the opinion of a large authority like yours as to the number of dilutions which it is prepared to ask them to treat?—But the increase of population itself would create the same difficulty. Supposing they construct their sewers to deal with six times the dry weather flow now, in a few years' time these sewers would be too small; in any case they would have to have a margin.

20464. Evidently, but a wise authority would look ahead, would it not?—It would look forward.

20465. And in laying down its sewers, would consider what has been the expansion of its population in the past, and form some opinion as to what it would be, probably, say in 20 years, in the future?—Yes.

20466. (*Major Gen. Carey.*) There is one point I wish rather to get cleared up. The Local Government Board Provisional Regulations on the subject refer to the average dry weather flow of sewage in 24 hours?—Yes.

20467. Your dilutions are based on a maximum flow in the 24 hours?—Yes, that is so.

20468. Therefore, practically the amount, six dilutions of sewage in 24 hours on the Local Government Board basis, would mean far less a volume than on the basis that you mentioned?—Certainly, it would.

20469. Therefore, supposing a place provided for six dilutions of sewage on the 24 hours average it would probably and almost certainly be providing for a very much less dilution than on the maximum in the 24 hours?—That is so.

20470. That ought to be taken into consideration?—That ought to be taken into consideration. That is a very important point.

20471. All your answers on this question have been based on the maximum flow in the 24 hours?—That is so. For instance, if we take the Stockport returns, dilutions of 3, 4, and 4 times.

20472. Yes?—Whereas the actual discharge to the outfall works was only $2\frac{3}{4}$ times the average dry weather flow.

20473. In the 24 hours?—Yes, in the 24 hours; we have been speaking all through as regards the rate of flow.

(*Chairman.*) It only remains for me, on behalf of the Commission, to thank you for the great trouble you have taken in getting up these data for us, and in coming to day to give us your opinion on these important points. We are very much obliged to you.

Mr. E. HALLIWELL, called; and Examined.

Mr. E. Halliwell.

9 Dec. 1904.

20474. (*Chairman.*) You are the Chief Inspector of the Ribble Joint Committee?—I am, sir.

20475. You have been good enough to come here to-day for the purpose of enabling us to get your opinion in regard to various matters. In the first instance, in regard to the evils that are produced by the sludging of the mill dams. Would you be good enough, in your own words, to tell us the nature of these dams in your district, whether they are situated mainly upon polluted or unpolluted streams, and the nature of the evils that arise from dam sludging in either case?—The dams, sir, in the Ribble Watershed are situate, as a rule, on polluted streams. They are of various sorts, constructed in different ways. Some of them, although on polluted streams—I ought to say that they discharge into polluted streams—collect the waters from small tributaries which are clean streams. Another class of mill dams are those which take in polluted waters, and are made in the manufacturers' works. Another class which is very prevalent in the watershed is that class which on a polluted stream is made in the bed of the stream, the manufacturer places a weir below the end of his works, at least as near as convenient, and, in some cases, dams up the river for a very considerable distance. The distance will vary according to the nature and fall of the river. The methods of sludging of dams are very variable. We had one case some few years ago where a manufacturer wished to clean a fresh water dam. Previously there had been a case taken into Court, and it was held that a manufacturer is permitted, under certain circumstances, to sludge his dam. The firm, to keep within the law, instead of sending men in with rakes or spades, connected pipes to the water supply, and after running off the top water from the dam they washed in from the bottom the accumulated matter by the force of water which they obtained from their hose pipes; they therefore managed without sending anybody into the dam to get rid of the whole of the accumulated matter. That is one form of sludging of fresh water dams. I will give you examples of the sludging of other classes of dams. On the River Darwen, one of our main streams, there are a very large number of dams which are sludged in some cases once or twice a year, generally at holiday times, and in other cases once or twice a month. The top water is first run off, and then the whole, or part of the river, is diverted through the dam. The large volume of water removes a large amount of sediment; but if the whole has not been entirely removed, the water is diverted by means of boards or planks into a fresh portion of the same dam. The force of water removes still more of the sediment, and with a little management the whole of the deposited matter is washed out into the stream.

20476. I suppose it does not really very much matter what process they employ to get rid of it, whether washing it out with the water supply by means of the hose, or pushing it with spades or rakes, or washing it out by diverting the river into it; it all comes to the same thing; it is washed out of the dam into the stream?—It is washed out into the stream.

20477. Now, does any evil arise from that?—Yes, sir; the streams are, when this is going on, extremely foul. Some distance below the dam you will find that the river is in a most polluted condition. On Saturdays it is quite a common occurrence to find the river on a Saturday afternoon, from 12 o'clock till late, according to the position you are taking up on the river bank, you will find the river black, and in the summer months stinking.

20478. There is a great excess of suspended matter for one thing?—Yes, that is so.

20478*. You have, I think, given us some data and analyses which have been made under your direction, in which we find, for instance, that the river Darwen, above Scotshaw Brook Mill, had nominally about four parts per 100,000 of suspended matter in it, but below the dam, during sledging operations the river Darwen had 244 parts per 100,000?—That is so, sir.

20479. So that there is evidently an enormous increase in the suspended matter?—Yes.

20480. It is not only that there is a great increase in the suspended matter, but I suppose it is the character of the suspended matter which adds to the objection?—That is so.

20481. The suspended matter being in a putrefying condition?—That is so. I should like to make a correction here; in the case you have mentioned, Scotshaw Brook, it was not exactly a dam, it was a goit, and goits are very similar in their action to the dams. From the point of intake to the point of discharge is a distance of about 300 yards, but the goit continues to a mill, a distance of half a mile.

20482. I suppose suspended matter settles in the goit, and when that suspended matter becomes inconvenient in volume it is let out?—That is so.

20483. So the action of the goit is only differing in degree from the action of the dam?—That is so.

20484. Now, as to the extent of the nuisance, there is obviously a large increase of suspended matter; is there are no appreciable stink from a discharging dam?—Yes, sir, there is undoubtedly.

20485. Have you had any complaints?—We have had informal complaints from manufacturers; they say the river is always very bad on Saturday; they do not care to write and make a formal complaint—they make these complaints to the inspectors when they visit. But in addition to that there has been a very bitter complaint. It has not been forwarded to us; I believe the letter has been sent to the Local Government Board—of that I am certain. But the Wigan Borough suffers very severely from this same sort of thing, running off the top water of mill dams, which carries away a lot of the suspended matter. The papers nearly every week contain letters, and remarks are made in the Council meeting nearly every meeting during the summer of the condition of the river, and that, I am confident, is entirely due to the running off of these mill dams and the removal of this suspended matter in this way.

20486. Then we are to take it from you that you have had complaints, many complaints, and that you are satisfied that it is a very real evil?—I am, sir.

20487. Now you have attempted to remove it by bringing actions against certain persons, and notably there is the case of the Ribble Joint Committee *v.* Halliwell, is there not?—Yes, sir.

20488. What was the result of that litigation?—The case was dismissed, sir; it was held that no offence had been committed.

20489. The case was appealed against?—The case was appealed against.

20490. And the judgment was confirmed?—And the judgment was confirmed.

20491. Now, what were the grounds of the dismissal of the case?—The grounds were that the matter was matter in suspension and not solid matter, and therefore the section of the Act——

20492. Which Act?—The Act of 1876.

20493. The Rivers Pollution (Prevention) Act?—Yes.

20494. Is there an exception made in regard to the matter in suspension coming down the stream?—Yes, sir.

20495. Do you happen to remember where it is?—It is in the Definitions, sir; "solid matter shall not include matter in suspension."

20496. Well, any way, there is an exception which appears to permit of this being done?—That is so.

20497. The existing law, therefore, you found to be insufficient to enable you to prevent the evils arising from dam sludging?—Yes, sir; also it was held—Judge Coventry stated that if he were wrong on this point of it being matter in suspension the firm were entitled to do it under Section 17.

20498. I see the section says that the Act shall not apply to or affect the legal exercise of any rights of impounding or diverting water?—That is so.

20499. Then Judge Coventry in this case held that that permitted these persons, even if there was pollution by dam sludging, to hold up the water?—That is so, and that was confirmed in the High Court.

20500. Then clearly you found that under the existing law you are unable effectively to prevent this?—That is so.

20501. You do not find the manufacturers are disposed to submit themselves to control as to the times of

Mr. E. Halliwell.

9 Dec. 1904

discharge, and so on?—No, sir; we have not pressed them to do that.

20502. But, any way, you have been unable to get them to remove from their dams the deposit in such a way as it shall not go into the stream?—That is so.

20503-4. What modification of the law in your opinion would be required and would be justified by the circumstances?—I think, sir, that one might reasonably ask at least that the law should be that when the top water from the dam has been run off, the matter which does not run off with that top water should be removed. You can run off your top water and leave a very great deal of the sediment at the bottom of the dam. The sediment, to my mind, should be removed in some way other than by the river.

20505. It should be put on to land, I suppose, carted away or taken away, or removed by some means on to land?—That is so.

20506. And is that, do you think, financially practicable in most cases?—I think so.

20507. Do any of your people in fact do that?—In one case, sir, they do indirectly; they do not do it in exactly the same way, but we have one case where there is a large dam. For reasons—the size of the dam and the difficulty of filling that dam again—they are unable to run off the top water, and frequently during the year a man removes the suspended matter from the bottom of the dam.

20508. Without emptying the dam?—Without emptying the dam.

20509. Does he do it by means of a boat?—He does it by means of a large raft, and by scooping the sediment from the bottom of the dam.

20510. On to the raft?—On to the raft, and then that is removed on to the land. That is done I do not think necessarily to suit us, but because of their own convenience.

20511. (*Mr. Power.*) Is this stuff supposed to have manurial value when it is recovered in that way, or has it simply to be got rid of as detritus of no worth?—I should think it would have very small manurial value.

20512. Do they use it as top dressing for pasture?—No, sir; I do not think it would be even worth that.

20513. (*Chairman.*) The fact that a certain firm is able to do this, and it is not found to be a ruinous expense, leads you to think that it would be a fair thing to ask all dam owners to deal with sludge in the same way?—Yes, sir.

20514. You think that is really necessary?—I do.

20515. You do not think that the mere controlling of the manner and times of the discharge would be sufficient?—You are bound to have a nuisance, sir, in any case, even if you control it. In the case of dams which are situate in the stream, which are built in the stream, to my mind it is impossible to insist on the removal of the suspended matter, because the matter settles in the river bed. Even if he runs off the top water, he cannot send a cart in to remove the sludge; he will do it at the time when there is heavy rain, when the river is coming down in more or less flood; it will remove the sediment, and even if the men were willing to have the means of removing it, the river coming down in volume would prevent them doing so, so that they would naturally, I take it, run off their top water at times when there was likely to be a flood; then the river coming down would remove the accumulated sediment in the dams, those of the dams which are situated in the river bed.

20516. In those cases you think it is not practicable to insist upon the persons using them removing out of the river altogether this suspended matter?—I think it is impracticable.

20517. It is impracticable in most cases?—Yes, sir.

20518. And in those cases would you do anything in the way of regulation?—I should.

20519. You think that would be useful?—I think it would be necessary, sir.

20520-1. You think at present, in the absence of any special clause in your own Act, the law does not allow you to prevent the evils of dam sludging, but the law should be modified with the view to permit two things—the control of the discharge, and the absolute removal in certain cases of the deposited matter on to the land?—That is so. Might I point out, sir, while you are speaking of the evils of sludging, that the table which I have submitted shows more clearly than the case of the Scotshaw Brook the evils of dam sludging.

TABLE referred to by MR. HALLIWELL.

RESULTS IN PARTS PER 100,000.

STREAM STATION.	Time.	Total solids.	Solids in suspension.			Solids in solution.			Ammonia.		Oxygen absorbed. Total.		Oxygen absorbed in solution.	
			Loss.	Ash.	Total.	Loss.	Ash.	Total.	Free.	Albuminoid.	15 minutes.	4 hours.	15 minutes.	4 hours.
River Blakewater -	9.0 to 11.30	46·8	·8	·0	·8	12	34	46	·2	·05	·4	·9	·36	·6
Do. do. -	11.30 to 1.30	55·2	3·6	5·6	9·2	14	32	46	·21	·095	·7	1·56	·42	·68
Do. do. -	1.30 to 3.0	59·0	10·8	9·2	20·0	13	36	49	·26	·172	1·16	4·24	·56	1·16
River Darwen -	9.30 to 11.30	68·6	3·2	2·4	5·6	21	42	63	·28	·21	1·34	3·2	1·02	2·18
Do. do. -	11 30 to 1.30	100·6	19·2	20·4	39·6	18	43	61	·29	·25	3·08	7·94	1·44	2·68
Do. do. -	1.30 to 3.0	63·7	2·3	3·4	5·7	14	44	58	·29	·23	1·3	3·18	·9	2·14

20522. (*Chairman.*) Yes?—In that case the samples were taken over a period of two hours, and you will note that the average suspended matter was 5·6. Then samples were taken from half-past 11 to half-past 1, two hours again, and during the whole of that time the average for that time the suspended matter was 39·6. The oxygen test you see shows that the figures increased from 3·2 to 7·94, showing that the suspended matter does contain a great deal of organic matter. Then from half-past 1 to 3 o'clock the river has again come back to almost its normal state, a very large decrease in suspended matter, and the oxygen absorbed is very much the same as it was early in the morning.

20523. So that during the sludging of the dam the suspended matter in the river was increased about eight times in the case of the River Darwen?—Yes, about eight times.

20524. And considerably more than that, about 20 times, in the case of the River Blakewater?—That is so; and, of course, one of the main evils in this case, the Blakewater and the Darwen, is the fact that after it has passed the district where these dams are situate, some few miles below the stream you have weirs built in the streams, and this large accumulation of suspended matter which has come down settles behind these weirs and gives rise to a very great nuisance.

20525. Then I will pass on, Mr. Halliwell, to ask your views in regard to the possibility of dividing streams or watersheds into zones, and having different standards of purification applicable to each. Do you think that variable standards applicable to different conditions and different parts of a stream or watershed are desirable?—I do not, sir.

20526. Will you tell us why?—I think that it would be as easy and as practicable for a Rivers Board or any other authority to judge each works on its own merits, as to form different zones on one river, or put rivers into different zones. The conditions are so very, very variable. The volume in some of our cases of the river in dry weather is almost entirely manufacturers' effluent or sewage effluent. After a little rain one river is washed out, and that rain is felt for some days. In another river after dry weather almost the same amount of rainfall has not the same effect. The greater portion of the rainfall passes very quickly, and even if it does not pass quickly a great deal of it is collected in reservoirs and very large fresh water dams for manufacturers.

20527. You are not in favour therefore of varying standards according to the circumstances of different parts of a stream; you have told us why?—No, I am not.

20528. But I rather gather you are not in favour of fixed standards at all, are you?—I am not, sir.

20529. You have been good enough before to express to us an opinion in writing upon that; would it be possible for you now briefly to restate it?—I think, sir, that if you fix a standard you will have to fix that standard so that in no case where the effluent exceeds that standard would you get pollution of the stream. I think you would find that many effluents which exceed that standard would not cause pollution. In some cases you would get effluents containing more organic matter than the standard permits of, but owing to the volume of the stream or the rapid flow of the stream that such an effluent, although above the limit, would not cause pollution. I also think, sir, that the volume and nature of trade refuse, which is very, very variable in its constitution in the sewers, ought to be considered; also one town which contains in its sewage a great deal of fæcal matter and urinal matter, and another town which contains less fæcal matter owing to the different systems in use in those towns, would make it extremely difficult to fix a standard, the same standard for the two towns. Also, sir, I think that when you have in one town a separate system for the storm water, and, in another, the combined system where they take the whole of their water, the effect of these waters on the sewage is such that it would be very difficult to fix the standards to meet the two cases. I also think, sir, with all due deference, that we hardly know as yet how far sewage treatment is practicable.

20530. Your objection is rather to the fixing of a standard at present than to the fixing of a standard at all?—I am not in favour of a standard.

20531. As a fact, you work upon a sort of gradual standard now, do you not?—We do.

20532. So that you do find it useful and practicable to have that standard, although it may be absolutely a provisional one?—We do, sir.

20533. Should you think a standard ought to be based upon the non-putrescibility of an effluent undiluted?—To some extent, but an effluent may be putrescible under certain conditions, whereas the analysis, unless very complete, would not show putrescence. And also, sir, we have our streams containing a very large amount of manufacturers' effluent, the trade effluent may in itself not putresce, but it may have such an effect on the sewage effluent that you get the whole river putrescing.

20534. You mean that the standard should take into account that it is quite possible for an effluent to be non-putrescent by itself, but actually to bring about putrefaction when it is diluted with the volume of the stream?—I think it is quite possible.

20535. But is it not possible to cover that by making your standard such as, for instance, it should be based upon the amount of oxygen taken up at a given time?—I think, sir, the conditions in which it takes up the oxygen either alone or diluted are so very, very variable that if you fix your standard, in some cases your standard will say to you that this man is committing an offence when he really is not committing one, or *vice versa*.

20536. Dr. McGowan, would you like to ask Mr. Halliwell anything upon this point?

20537. (*Dr. McGowan.*) I did not quite follow an answer of Mr. Halliwell's just now; I might ask him to enlarge it a little. You said that you might have an effluent which was non-putrescible in itself, but that if it went into a stream it might cause putrescence in that stream; but then is that not because the stream water was a worse effluent than itself?—That is so.

20538. So that as a matter of fact you are talking of running an effluent which would be classed as non-putrescible into an effluent which would be classed as putrescible, but under the name of stream?—Yes, sir, it is a question as to whether you could make a sewage effluent standard applicable to a manufacturers' effluent standard.

20539. Had you any instance in mind when you made that answer about an effluent non-putrescible becoming putrescent when it goes into a stream?—I cannot put my hand upon a definite case; I believe it is the case in some of our streams.

20540. It is a most interesting point, and if you could give us some information on that point we should like to have it?—I am judging from these grounds, sir. I do not doubt the whole volume of some of our streams in summer is entirely manufacturers' effluent, plus some sewage effluent; below the point of the last receiving of sewage effluent there are several large weirs, now behind those weirs there is a nuisance; higher up the stream where the weirs are not present, you cannot complain of the condition of the stream.

20541. Then, I take it, probably the nuisance arises behind the weirs from the accumulation of solid matter?—That is so.

20542. So if your standard made provision as regards solid matter you would probably avoid that, would you not?—Well, sir, I have several cases in mind where an effluent itself is not putrescent. If you take the Accrington samples, which you will probably know of, the sample itself will not putresce, but if you allow the sample to settle for a little while, pour off the top water, add fresh water to the sediment which has settled out, that sediment will take up the dissolved oxygen from the water; and I take it it is the same thing that happens in the stream. Take the Accrington case; the nitrates present in the supernatant liquor are sufficient to prevent that liquor putrescing, but the suspended matter which, although small in the effluent itself, accumulates behind these weirs, and in the goits and the dams, the supernatant water is passed, and you get the sediment due to this accumulation of matter, putrescible, and setting up putrescence in the whole river. Now, we have several cases of that sort. Of course, on the other rivers, on the Ribble itself, which is a large stream and in good condition, I do not think that you would have anything like the same effect; I do not think it would be felt as the water passes away—it is not held up to any considerable extent—and we should not have the same nuisance. But take the Douglas, another of our main rivers. The whole volume of the river in dry weather is passed through a manufacturer's mill dam, and an opportunity given for any or all of the suspended matter to be deposited. Above this point there is a sewage works, and a very large volume of trade effluent, several million gallons, everything goes into the milldam, settles, and causes putrescence. It is on those lines which I think prevent you fixing the standard, because it depends on the local circumstances of the river, some distance below the point of the effluents which you are judging.

20543. There is just one more question, if I might ask you, Mr. Halliwell. You say that at present you do not think it would be advisable to fix a standard; you are not absolutely against a standard. Supposing you were in a position to fix a standard, have you formed any idea in your own mind as to the principles upon which you would base the standard?—Yes, sir. The first strict rule, to my mind, would be the removal of the suspended matter; I was going to say almost the entire removal of it. I think three parts per 100,000 would in some cases be not severe enough. It is the accumulation of it which I fear so much. After the removal of the suspended matter, I think one should judge of the rate and amount of dissolved oxygen which that effluent should take up; both the amount and the rate, not necessarily one, but both together. I also think, of

Mr. E. Halliwell.

9 Dec. 1904.

course, that absorption depends more or less upon the nitrates present in your effluent. In sewage effluents, I think, you ought to have nitrates present to some extent, not necessarily a very large extent. Of course, some classes of effluents do not contain so much nitrate as other classes do, although the one containing less nitrate might be a better effluent than the one containing a large amount.

20544. What would be the object of having nitrate present in the standard?—If you have nitrate present it shows that nitrification to some extent has gone on; it has reached that point where further nitrification could go on.

20545. (*Chairman.*) The effect of dissolved oxygen in the effluent would be the same, would it not—that you would get oxygen there to complete the purification of the remaining organic matter?—Yes, sir, of course you would.

20546. So it is immaterial whether the oxygen exists in the form of nitrates or in the form simply of dissolved oxygen?—I say I should require more than that; I should want the effluent to contain dissolved oxygen in addition to the nitrate.

20547. The practical point you were putting before us, which interests us very much, is that you think the measure of the dissolved oxygen taken up by an effluent is a valuable test?—I do.

20548. And that that, in connection with the amount of suspended matter, might be a sufficient test?—I would not like to go so far as that, sir; those points I think ought to be considered.

20549. What points?—The amount of the dissolved oxygen, and the rate at which that dissolved oxygen is taken up or disappears, whichever way you like to take it; and the entire removal of the suspended matter. But at the same time I also think that the others ought to be considered—the other points, such as oxygen absorbed and nitrogeneous matter, should be considered.

20550. But suppose an effluent passed a reasonable standard in connection with dissolved oxygen, would you not be satisfied with it?—My difficulty, sir, would be to fix a standard for the dissolved oxygen. It should perpaps be on those fines, but personally I could not say what figures would satisfy our watershed.

20551. Well, let me put an example before you. Suppose you have an effluent, and you shake it up and you saturate it, and after 24 hours you still find it contains half its dissolved oxygen, would you consider that satisfactory?—After 24 hours?

20552. Yes?—Not in itself.

20553. You would think it necessary to investigate it further?—I do, and on these grounds—that some distance below where this effluent is discharged into the stream, the stream is used, or is probably used, by some manufacturer who increases the temperature very markedly of nearly the whole volume of the stream. Now if he does that you will probably find that he not only removes by increasing the temperature some of the dissolved oxygen, but he also tends to hasten any putrefaction which can occur. We feel in our watershed the usage of the water very severely. The temperature of the water of the rivers is distinctly high in many of our cases; it is so often used and re-used and used again by manufacturers either for condensing purposes or boiler purposes, or in some cases manufacturing purposes.

20554. Are we to gather that in your opinion, on account of the temperature of the streams in your district, you consider that an effluent which after 24 hours had not taken up more than half the dissolved oxygen, would still be objectionable?—I would rather put it this way, sir—that I am not sufficiently confident as to what would happen; I would rather not express an opinion. I think it is quite possible in some cases it would occur, but I cannot give you a definite case.

20555. Speaking generally, then, you would have confidence in a standard which was based upon the amount of oxygen taken up, and also upon a certain limitation of suspended matter?—I think these are the lines which should be considered.

20556. But you do not think it would be applicable in all cases?—No.

20557. With regard to zones, you think it is not desirable to divide into zones, but go much further and consider each specific case by itself?—Each specific case by itself.

20558. (*Major-General Carey.*) Do you modify your provisional standard according to the locality or position?—No, sir. The provisional standard is very useful in this respect, that in many of our works the committees and managers like to know how the results compare with other places, and they are interested in those results; they can understand a simple figure. But in some cases our provisional standard is affected by other things; I must admit in some cases the albuminoid ammonia standard is unsatisfactory; other figures would show it was satisfactory, and *vice versâ*. Those are considered by us before we take steps to compel further purification.

20559. (*Chairman.*) There remain one or two questions which I want to ask you on the important question of the treatment of storm waters. I suppose I may take it in your district not every local authority can be said at present to effectively treat even its dry weather flow?—Not every authority.

20560. Does any important authority in your district treat effectively not only its dry weather flow, but some dilutions beside?—They do.

20561. Tell us what you think is practicable to be done by local authorities so far as your experience goes. First tell us what you think it would be desirable to aim at doing in the direction of dilution, and then what you think it would be practicable to do—practicable, I mean, for financial reasons?—Certainly.

20562. First of all may I take it that you think many more than six volumes should be treated if you are to prevent the pollution of a stream?—I am afraid, sir, I hold rather different opinions in connection with storm water than I have ever seen expressed. I hold that at the beginning of a storm the whole of the waters should be treated whatever that volume happens to be at the time.

20563. It might rise, might it not, to a very large number of dilutions?—Yes, to a considerable number.

20564. Although you may think that theoretically it ought to be done, you are limited by such considerations as the area of the sewers, for instance?—Undoubtedly. The sewers will take at the beginning of a storm—in most cases that we have to deal with, ordinary sewers will take the first half-hour's rain at any rate, as a rule; it must be a very heavy rainfall that is not taken into the sewers. At the beginning of a storm the sewage is incomparably worse than the ordinary dry weather flow.

20565. Your view, then, is the same we have heard expressed in other directions—that the early dilutions of sewage are much worse than the dry weather flow was?—Undoubtedly.

20566. And even with six dilutions that is the case?—That is so. It depends largely, sir, upon several points, important points. Firstly, it depends on the incline of the sewers and the conditions of the sewers. There is one case in our watershed where at the beginning of a storm the overflow is extremely bad; in that case it is an oldish town, the sewers have been laid for many years, and have more or less sunk. The result is that you get with a little storm the washing out of these sewers, which causes a discharge of a very strong sewage. And I might draw your attention to samples which I took from one town. In this case the samples of the sewage were taken every day for a week; they were average samples, taken, I believe, every 10 minutes for a period of one hour. The analyses were as follows:—August 7th, the suspended matter was 8.

20567. Eight there means 8 parts per 100,000?—Eight parts per 100,000; the next day it was 24; on the next day there was a storm, and samples were taken of the overflow to the river every 10 minutes for 1½ hours; the suspended matter was 370. The next day the suspended matter was 26; the next day it was 18·5; the following day there was another storm, and the suspended matter increased to 178. Now, in that town, sir, the sewers are, comparatively speaking, old; it is a colliery district, and there has been a great deal of subsidence. The normal sewage, I believe, is weaker than in most towns owing to a lot of the suspended matter settling in the sewers; if you get a storm the sewers are washed out completely.

20568. When you tell us that the storm sewage was worse, and even many times worse, than the dry weather flow, you would probably find, would you not, that it was due to an excess of suspended matter rather than of dissolved impurities; have you investigated that

point?—That is so; it is more in connection with the suspended matter, but the suspended matters are largely organic matters.

20569. Should I be right in taking your opinion to be this—that in storm waters the main thing to do is to settle the suspended matter?—Yes.

20570. Have you tried any experiments yourself in regard to storm waters, of filtering such storm waters, and then estimating the amount of dissolved impurities?—I have taken samples, sir, of storm water in which the treatment has been simply settlement or precipitation.

20571. Well?—And in that case it is quite sufficient.

20572. You find that what is left after unassisted settlement of storm waters may safely be allowed to pass?—I think so, sir, undoubtedly. My opinion is that if you remove the suspended matter you can safely allow the other to go. Not only is that matter in solution less polluting, but the river is probably in flood at the time, and can take that matter in solution without causing any nuisance; but the suspended matter if allowed to go forward would settle in the river. Another important feature is the amount of trade refuse in the sewers. In one case a little while back we had a sample from a storm water overflow during a storm which was very much worse than usually is the case. On investigation we found that at this particular time there was an excessive quantity of trade refuse going into the sewer. In this case the manufacturer had an agreement with the Corporation to take the worst portions of his trade refuse.

20573. You say "too big"; do you mean to take into the sewers?—Yes; the manufacturer passes his trade refuse into tanks; the letting off of these tanks is in the hands of the local authority; they can let them off as they wish. The tanks were full, or nearly full; the man who had control of the tanks discharged the tanks into the sewers at the time when the sewers were charged with rain, the result was that most of the manufacturers' trade refuse went through the storm water overflow into the river. That may be an exceptional case, but it did happen. The authority, on this case being pointed out to them, said they would in future take more care.

20574. Even in your own district that was an exceptional case, was it?—I think so, but it may happen, and is very likely to happen; so that to my mind you must consider, on the question of storm water overflows, the amount of trade refuse, and the nature of the trade refuse, which is going into the sewers.

20575. But, speaking generally, we have got your opinion so far that storm waters are exceedingly impure, but their impurity is mainly due to suspended matter?—That is so.

20576. The settlement of such suspended matter, speaking generally and broadly, would be sufficient treatment?—That is so.

20577. The next point we want to get at is how many volumes is it practicable to ask authorities to deal with?—I have considered that point, sir, and I think the volume they should deal with depends on the distance of the sewage works from the town, and also the nature of the town. I might, for example, point out: We have in one case a town in which the sewage works are close to the town; it is a hilly district. At the beginning of the storm the rain passes quickly into the sewers and gets away; the sewers do not feel the effect of that storm for any length of time; but in other cases the sewage works may be some distance away, and the sewers having a slow gradient, the sewage does not get to the sewage works in the same time; and, therefore, if you have your storm water overflows made in several places you will take to your sewage works a very great deal less liquid than a town where the sewage works are close at hand.

20578. You think that whatever rule is adopted such rule cannot be applicable in all cases?—I think so, sir.

20579. Are you able to express an opinion upon the provisional rule, which has been laid down by the Local Government Board as a condition for sanctioning the loans, as to whether the six times, which are to be treated, partially and wholly, meet the case?—I do not think they meet the case.

20580. You think that more should be done?—I think there should be more latitude shown. If possible they ought to treat more than six times at the beginning of the storm, and afterwards, I think, it is quite feasible that less than six times should be treated.

20581. Then that would involve, would it, a storage?—It would involve a storage.

20582. You would not suggest that the works should be enlarged so as to deal with a larger number of volumes than six, even for short periods?—I think, sir, for a short period it is possible to deal with more than six, and that is done in our own watershed.

20583. In other words, you think it is possible to overwork the plant for a limited period?—I do. You have to treat say up to three times as normal sewage, and from three to six as storm water sewage. It is often argued in the district that if you can pass into the stream effluent from sewage which only needs partial treatment, that is to say, from the three to the six, you ought only to treat partially the one to six, and in some cases they do that; but they store the first portion of their sewage; then when the sewage is diluted they will only give it a partial treatment, but they will be treating fully the sewage which they have stored, which is the strongest portion.

20584. The mere storage involves very considerable outlay, does it not?—It depends very largely. In some cases they can afford to do it. In some of the normal plant they can reserve a tank or tanks for the first portion of the storm sewage, whatever strength that may be.

20585. Are the sewers as a rule capable of bringing down more than six volumes?—In some cases they are and in others they are not; in some cases they cannot take six times under any conditions; but as a rule the main storm overflow is at the works.

20586. So that you could not carry out your suggestion to advocate that not only six but more than six, except by duplicating the main sewers in those places?—The length of sewer which would need duplicating is very variable; they often have sufficient sewers, the sewers are sufficiently large to take over six times to a certain point, and the duplication of sewer might only mean in some cases, comparatively speaking, a small length.

20587. We may take it as your view that, speaking generally, the treatment of six volumes, some of them thoroughly and some of them partially, is a fair thing to ask the authority to do, but that you think in the beginnings of storms, even more should be done?—I do.

20588. Now, is it practicable to do that financially; have you in your district any authority that is dealing with six volumes of its dry weather flow?—We have several.

20589. Would you name some to us?—Brierfield are dealing with at least six times the dry weather flow.

20590. What is the population?—I believe the population is about 10,000.

20591. Are there many such authorities in your district?—Several are treating at least six times dry weather flow. Darwen is the case where they take the whole of it, whatever it happens to be.

20592. That the sewers bring down?—Yes; and the sewers bring far more than six times, and they deal with it for a time.

20593. In expressing to us an opinion that it is financially practicable for authorities to deal with six volumes, you are basing your opinion on the fact that that is actually done by certain authorities in your district?—That it is actually done by certain authorities.

20594. You told us in your earlier evidence that you thought it inadvisable to have fixed standards because they could not be applicable in all places, not even in zones, upon a stream, but that they must be considered in relation to the particular merits of each case on the river; therefore, after fixing the number of volumes to be treated, you must also be guided in each case by the local circumstances?—Undoubtedly.

20595. You do not think it practicable to lay down any general rule?—I think it is impossible, and one of my reasons for objecting to standards is the fact of the presence of storm water; the storm water question is one of the main features to my mind for objecting to standards.

20596. Would there not be very great difficulty with the Local Government Board or any supervising autho-

Mr. E. Halliwell.

9 Dec. 1904.

rity in considering a scheme if they had not in their minds some sort of standard as to the amount of capacity that sewers should have?—Undoubtedly it is a difficulty, but I think it is less difficult to consider a place on its merits, and there is less likelihood of granting favours to one place and disfavours to another if you consider it on its merits rather than put down a fixed standard.

20597. Considering each case on its merits, what is to be the basis of your decision?—I think it would be quite possible that samples should be taken and the volume of liquid measured at frequent intervals. After considering the analyses and volumes you should be able to say when the storm water overflow should be allowed to come into operation.

20598. The quality of the storm water would be the basis of the decision that you would come to in each case?—No, not the quantity; I should take it on the nature of the overflow, not on the quantity—on the nature of it.

20599. What do you mean by the nature if not the quality?—I beg your pardon; I thought you said quantity.

20600. No, I said quality?—Quality—I should, sir. If I might mention one matter in the question of storm overflows, we have a case in point. There is an authority discharging from a storm water overflow which does not come into operation until more than six times dry weather flow is passing; but that overflow goes to a river which is impounded in its lower reaches by a manufacturer. The manufacturer complains to us that this stream is polluted. I do not think this particular overflow comes into operation until 10 times the dry weather flow is passing down. The authorities say, "If we treat six times, the Local Government Board say we are justified in passing into the stream," but undoubtedly the manufacturer has some reason for complaint. Here again it is a question of the stream into which the storm overflow discharges, and therefore not only must you consider the quality of your overflow, and the quantity of your overflow, but you must consider the river into which it overflows.

20601. Thank you, Mr. Halliwell; we are much obliged to you for coming to us and giving us the valuable evidence you have given us to-day.

Copy Letter from the Ribble Joint Committee.

(*Secretary.*)

Ribble Joint Committee.
County Offices, Preston,
8th December, 1904.

Sir,—I am directed by the Ribble Joint Committee to draw the attention of the Royal Commission to the question of amending the Rivers Pollution Prevention Act, 1876, in order that a certain class of offence which is causing the greatest possible harm to the rivers in this watershed may be more readily dealt with by local authorities entrusted with the carrying out of the Act than is possible as the law now stands. During the 13 years that the Joint Committee has been in existence a considerable amount of work has been done in getting manufacturers to put down purification plant, but occasionally some manufacturers are detected running off their precipitating tanks, and thereby allowing the deposited solids at the bottom of the tanks to be carried away to the river. A case in point is a well-known paper company who were compelled by the action of the Ribble Joint Committee to construct purification works at their two mills, and on the 10th March last during the night time the precipitating tanks at each mill were run off simultaneously into the river, the offence being detected by the Rivers Inspector. On the 14th March the Committee decided to take proceedings; on the 30th March an application was made to the Local Government Board for an order to do so; the Board held an inquiry on the 6th May, and gave their consent on the 30th June; this was reported to the Joint Committee on the 11th July; and on the 23rd September an action was heard at Darwen County Court when the firm were ordered to abstain from committing similar offences in the future, and to pay the costs. Upwards of six months elapsed from the date the offence was committed before the matter could be brought before the County Court. The order of the court did not require the firm to construct additional works, but simply to make proper use of those already existing.

The Committee are of opinion that it ought not to be necessary in a case of this kind to obtain the sanction of the Local Government Board before taking a case into the County Court to obtain an order compelling the manufacturers to refrain from making improper use of existing purification plant.

I enclose particulars of several other cases of a similar kind, showing that the practice of running off precipitating tanks surreptitiously is by no means an uncommon occurrence, and is one which is difficult to stamp out, as the law now stands.

The Committee beg to suggest that the law might usefully be amended in this direction, and further that the County Court should have power to inflict such a fine as the Judge might think proper, having regard to the circumstances of the case. At present the County Court cannot inflict a fine, except in a case where an order has been previously made by the court and disobeyed.—I am, Sir,

Your obedient Servant,
H. E. Clare,
Clerk to the Joint Committee.

Enclosures to Letter from Ribble Joint Committee.

Ribble Watershed Joint Committee.

At a meeting of the Joint Committee to enforce the provisions of the Rivers Pollution Prevention Act, 1876, in relation to parts of the River Ribble, held at the County Offices, in Preston, on Monday, the 12th day of September, 1904.

PRESENT:—

The Right Hon. Sir J. T. Hibbert, K.C.B. (Chairman), etc., etc.

Suggested Amendment to the Rivers Pollution Prevention Act, 1876.

Resolved.—That a recommendation be made to the Royal Commission on Sewage Disposal that in any further legislation relating to rivers pollution it should be made an offence, punishable by a fine, for any person to wilfully misuse works which have been constructed for dealing with the effluent proceeding from a manufactory or manufacturing process, and that in such a case it should not be necessary to obtain the consent of the Local Government Board before taking proceedings.

H. E. Clare,
Clerk to the Joint Committee.

Royal Commission on Sewage Disposal.

EDWARD HALLIWELL, F.I.C.

DR. GEORGE REID, called in; and Examined.

Dr. George Reid.

9 Dec. 1904.

20602. *(Chairman.)* You are medical officer of health of the Staffordshire County Council?—Yes, sir, I am.

20603. And in that capacity you have had very considerable experience of sewage treatment and sewage works, and we should be very pleased to have your opinion to-day upon certain specific matters. You are, I understand, to give us some evidence on the other matters at a later date. First, in regard to your experience as to the best tests for sewage effluents, would you be good enough to say what tests you use yourself and how far you find them reliable?—I use the free and albuminoid ammonia tests, the oxygen absorbed in four hours at 80° F., the nitrate nitrogen, and I always estimate the solids in suspension and in solution, and the chlorine; also, we have in Staffordshire a standard of opacity which is one I introduced some ten years ago. The standard is a disc at the bottom of a 2-foot cube with certain lines, fine cross lines. The tube is graduated into half inches, so that we are then able to put down a certain figure representing the opacity of the effluent for what it is worth. I believe that the same standard has been adopted in several other counties since we started it in Stafford. I intended to have brought this particular disc with me to have shown it, but I have forgotten to.

20604. Do you find the test as to opacity of great value?—Well, it is not of great value, but it is useful when you come to look at the figures some years hence, as it may throw some light on some rather extraordinary results. You may then by this opacity test be able to say, "Oh! but it was a horribly filthy-looking stuff."

20605. An effluent might analyse very well, but where there was an opalescence it probably would tell against it?—It would in that case, and to that extent I would discard it. There are certain works, for example, that we get our regular clear effluents from, and if suddenly those works should begin to show an opaque effluent figure I should think there would be something wrong, simply from that fact only, apart from the other figures, and probably it would be accounted for by something happening in the management that was wrong. It is not an important thing at all, but there it is; it is not easy to describe the appearance of an effluent, and it obviates the necessity for describing it if you are able simply to use a figure.

20606. Have you found your oxygen absorbed and albuminoid ammonia test to be generally sufficient and reliable?—I think so.

20607. Do you pay much attention to the incubator test?—No, I have not done so. The reason for that is that in Staffordshire effluents are either bad or good; that is the position at present. The modern works in Staffordshire are practically all good works, and it would be needless to go through the incubator test, because the effluents, on the face of it, could not putrefy—the amount of nitrates in them compared with the amount of organic nitrogen is such that they could not putrefy.

20608. Have you used to any extent or at all the dissolved oxygen test?—No, not at all.

20609. Should you consider that that test by itself might be sufficient for a good effluent?—I am afraid I should not like to say that it would be.

20610. It is a matter to which you have not given any personal attention?—No, I have not.

20611. I am very sorry that my colleague Sir William Ramsay is not here to-day; probably he might have been glad on these technical points of the oppor-

tunity of putting some questions; in his absence I would ask Dr. McGowan if he would like to ask any questions bearing on this question of tests.

20612. (*Dr. McGowan.*) I do not think I have much to add to what you have just said. In the summary of evidence, which you sent in, you say: "In judging of the quality of an effluent, various analytical figures have to be taken into account, and, as the significance of each is governed by the others, it would not be feasible to fix a definite individual minimum." Here is the point I wanted to ask you about: "Moreover, it would be misleading and erroneous to base a standard upon one figure, because the limit within which that figure might vary in a good effluent is considerable, taking other figures into account"?—Yes.

20613. I do not quite follow that sentence; it is a crucial sentence, and I do not quite gather what your view is?—This is the point. Supposing you have a certain quantity of organic ammonia, say 0·08 of organic ammonia and a very small nitrate nitrogen figure, it is quite possible that that would be a polluting effluent. On the other hand, you might have a larger amount than 0·1 of organic ammonia, and with that a high nitrate nitrogen figure, in which case it might not be a polluting effluent. That is my point with regard to that; that is to say, you have a certain amount of available oxygen in your effluent to be liberated and to carry on the work after the treatment is over, and that is, I think, one great difficulty in arriving at one figure as a basis for a standard.

20614. (*Chairman.*) In any case what you are aiming at is to ascertain the putrescibility or otherwise of an effluent?—That is so.

20615. (*Dr McGowan.*) But you have given no attention whatever to the rate at which an effluent takes up dissolved oxygen?—No, I have not, except I have formed a sort of impression, which impression has varied from time to time. I have never gone into the matter for the purpose of ascertaining that, but sometimes when samples have lain for some time in the laboratory I have come to the conclusion that they had lost nitrates, as they had been very much better when analysed sooner; I have never done anything systematically in order to arrive at an answer to that question.

20616. (*Chairman.*) The next point I would like to ask your opinion upon is the desirability of having standards at all for sewage effluent, and if you have a standard, how far it would be desirable to modify it according to the circumstances of streams in certain zones?—Yes; well, I think that it would be desirable if possible to have a standard; it would be a most convenient thing to be able simply to say: "You are not up to the standard, therefore you must do something more." But the difficulty of arriving at a standard is so great in my opinion that I do not think it is practicable to have an uniform standard. On the other hand, if some convenient method of arriving at a standard can chemically be laid down, and an accurate method devised, then I think it would be desirable to have a standard. But it should be made applicable to certain zones, as you say, and not to the country as a whole, because of the varying character of the districts, from the point of view of storm water, and the volume of the streams into which the effluents are to be discharged.

20617. Is there not another important point, namely, whether the waters of that stream are used for drinking purposes or not; ought not that to be taken into account?—Well, I am afraid I do not agree with that suggestion, because I do not think that any sewage disposal authority could, by any known method, at any rate, discharge an effluent which would be taken as satisfactory from the point of view of drinking water; and therefore it must involve further treatment of the water, and by laying down a standard from that point of view you would be asking the authority to deal with an enormous volume of fluid after it had been chemically purified—an enormous volume of fluid, one-sixth part of which, we will say, would have to be dealt with again from the point of view of drinking water by the drinking water authority lower down. It seems to me that the two authorities would in that case be doing the work seven times over, and when it was done you still have to consider the surplus storm water, which, I take it, you could not possibly deal with in that way.

20618. I gather when you speak of the standard being itself desirable it would be a chemical and not a bacteriological standard?—Quite so.

20619. You would not consider it necessary, therefore, that even where sewage effluents are passing into streams that are used for water supply, authorities should be called upon, to any extent, to sterilise such effluents?—Certainly not.

20620. You think that the work of eliminating organisms should be the work of the water-supplying authorities and not of the sewage-disposal authorities?—That is so; they have a much smaller quantity to handle to begin with, very much smaller.

20621. (*Major-Gen. Carey.*) What is your objection to sterilizing the effluent?—Well, first of all, I think that the cost would be enormous, of many methods that we know at present, the cost would be enormous; secondly, I do not think it would be practicable to sterilise all the discharges from the sewers, and unless you sterilise all the discharges from the sewers you would be misleading the public to some extent, that is to say, there would be a danger of a false security being established which might be dangerous at times. If you are going to establish a system of sterilisation you must sterilise everything you discharge from your sewers; if you do not do that, then the danger is very considerable.

20622. When you say everything you mean storm water in addition to sewage?—Yes. And apart from that, of course I do not know what form of sterilisation the Commission may have in view, but if it should be anything other than a mechanical sterilisation you would injure the stream in a sense, because you would not have the benefit of the purification which goes on afterwards if you turn a highly chemically purified effluent in; you get a great deal of the work done in the stream itself, but if you impose a certain condition with regard to sterilisation by certain methods you would then be turning in an inert fluid, in place of an active fluid with oxygen to do the work afterwards.

20623. By mechanical sterilisation I take it you mean very fine filtration?—Yes.

20624. (*Dr. Houston.*) As regards that last point sterilisation might actually improve the effluent from the point of view of purification. The last point that you raised was that you were frightened that if sterilisation were adopted the liquid going in would not be so pure?—Yes.

20625. But it probably would be purer if you used ozone or sodium hypochloride?—Yes.

20626. The liquid going in would be absolutely purer?—Except to this extent, you destroy the nitrifying organisms.

20627. That is a point that has to be considered, but, of course, those would be present in the river?—Yes.

20628. In some cases in rivers the waterworks authorities actually shut down the intake for waterworks purposes during a storm, so that it might not be absolutely necessary to sterilise all the storm water?—Yes.

20629. That is the case, I believe, on the Thames with some of the waterworks authorities; they close the intake during storms?—Yes.

20630. At least they say they do?—Yes.

20631. Then as regards cost? Would you consider £1 per million gallons prohibitive; that is as an adjunct to the rest of the treatment? You speak in your statement as if the Commission thought of sterilising raw sewage; I do not think the Commission have really considered the possibility of sterilising sewage; it would be always an adjunct if it was thought of at all?—Yes, quite so.

20632. So I do not think it need be considered except as an adjunct. Would you consider £1 per million gallons prohibitive?—I should say certainly. To what extent would you go in regard to dilution of storm water—to six times?

20633. Well, of course that raises another point, and a very difficult point, I admit.—Yes. The case depends largely upon that.

20634. As regards that storm water, you say the intended benefit would only be intermittently operative; but it is rather the other way round, the storm water would only be occasional; I mean it is hardly

Dr. George Reid.

9 Dec. 1904.

fair to put it that way?—Well, I did not mean to put it unfairly.

20635. Oh, I quite realise that. Of course the storm water is a very serious question?—If it cost £1 per million gallons it would cost Birmingham £130 a day.

20636. But there again is Birmingham a likely instance; in cases like that would sterilisation be likely to be necessary? It is more in cases, we will say, like the Thames or the Lee?—Yes.

20637. Where the last sewage works are just above the intakes of the waterworks company. If you sterilised there you would have a decided advantage, would you not, or might have?—Well, I do not quite know that you would have, because the water company could not by any possibility take that water to distribute it without further treatment.

20638. Well, there would be double security, would there not?—And if you have to treat it at all I do not see that you gain much by reducing the organisms beforehand. Surely a water filter, if it is effective, will take out a sufficient quantity, and it does not matter whether the number of organisms in that quantity is very great or very little, as long as they have to take them out.

20639. Yes, but then I fancy you would hold that filtration is only a relative safeguard; it is not an absolute safeguard?—Quite so.

20640. Whereas sterilisation is an absolute safeguard?—Yes; sterilisation is an absolute safeguard.

20641. In some cases there might be an economic advantage in sterilising the effluent and not the water, might there not? Suppose you have a waterworks that do not filter; they do not find it necessary to filter their water; it is a pure river, a pure stream, and there is a small town just above the intake discharging an effluent into it. Surely in such a case it might be an economical advantage to sterilise the effluent and not the water?—Then I think I would call upon the water authority to do it.

20642. That involves another question?—It does involve another question, but I think from the point of responsibility the water authority should do it.

20643. But on that very point the Commission have more power, have they not, as regards sewage disposal than as regards water?—Yes.

20644. I mean they have not received much evidence from waterworks officials?—No.

20645. And it is not so distinctly under the terms of their reference as the disposal of sewage?—No.

20646. And they could bring pressure to bear in certain cases on sewage disposal when they may not as regards water supplies—they cannot set up a code of ethics for waterworks authorities; that is a difficulty, is it not?—But the Commission might say this: Suppose the Commission come to the conclusion that in certain cases it is desirable to sterilise, they might express the opinion that in the opinion of the Commission it is the water authorities' duty, and not the sewage disposal authorities' duty, to do it. Otherwise, by reason of the accident of having lower down stream an authority taking water from that stream, you would be imposing a large expenditure on a sewage disposal authority, not because of any fault of theirs, but simply because they used the natural outlet for their effluents and the accidental circumstance comes in that there is a water company down below; so it is the water company in all cases who should do the work, not only from the point of view of payment, but from the point of view of having the responsibility placed upon them, because I do not think it would be right that the public should be at the mercy of a sewage disposal authority for the water that they drink; the water authority alone should be held responsible.

20647. (*Chairman.*) Then, proceeding, Dr. Reid, we would like very much to hear your opinion as to the extent to which storm waters should and can practically be treated?—Well, I do not think that the requirements of the Local Government Board are excessive in that respect; I think they are reasonable, in fact. I do not think an authority ought to be expected to go beyond that quantity. At the same time, there are local conditions which make it desirable to have provisos. For example, although six times the dry weather flow spread out over the 24 hours may be the amount, the works in certain cases should be so arranged that the first flush of a storm may not go into a stream even when that amount of dilution is reached. This involves the question of storage, and I think that in some cases it is desirable to have storage tanks for the first flush from the sewers; that is to say, even if it should be considerably beyond six times the dry weather flow for a certain period, and that after that period what comes down may go into the river, while the other is held back for treatment at the leisure of the authority.

20648. Would not that storage be rather a serious business; how many hours' flow would you suggest should be stored?—Well, it would not be many hours; it would be a comparatively small period in most cases. It is the first flush that comes from the sewer, particularly after a dry period, which is very foul, and if the sewers are on a steep gradient—I have a case in mind at the present moment in North Staffordshire, of a district called Tunstall—I do not know whether the Commissioners happen to know that district—but if you stand on the works and a little rain happens to come, an ordinary shower of rain, in the course of half an hour the overflow at the works is discharging straight into the stream and discharging very offensive sewage. Then, in a very short time, comparatively, the quality of that sewage improves very much, so that then it might go into the stream. They ought not to be allowed to turn anything over under six times the dry weather flow; but they ought to have the power of allowing more than that to go into a special tank. Of course, it is very difficult to say what storage should be provided—most difficult; so long as a tank is available and always empty it would be something gained, and the size might be regulated by local circumstances. Under the circumstances, I do not think you could lay down a strict rule with regard to the tank capacity; but you could, considering the contour of the district, and so on, probably arrive at a reasonable size for this tank, and granting that it is kept empty during dry weather and available for storm water, then when it is full the rest can go direct to stream after six times dilution. I think that is the only way by which you could arrive at a figure with regard to the volume to be so dealt with.

20649. As to the composition of storm waters, have you given that matter any attention?—No, I have not; not as to what extent it is affected by solids in suspension.

20650. Evidently the effect of the rain would not have increased the production of domestic sewage or trade effluents?—No; but it flushes down a large amount of deposit from the sewers of a very foul character.

20651. So that the foul condition of sewers, the accumulation in the sewers themselves, the gullies, and the washing down of roads, roofs, and so on?—Yes.

20652. And would be mainly suspended matter?—Yes; probably it is mainly that.

20653. Have you formed any opinion as to the sufficiency of settling suspended matters in storm waters? No; I have not.

20654. It might be interesting, if you are able to make any observations in your district, by separating out the suspended matters by filtration through paper and gauging the amount of dissolved impurities?—Yes; I could very easily do that.

20655. It would be interesting?—Except that one does not multiply those things: but I should be very pleased to do that. With regard to forming an opinion as to the capacity, one can judge very fairly of what happens in a detritus tank. In some cases you have a detritus tank upon a larger capacity per volume of sewage than in others, and you get a very large amount of suspended matter held back by the detritus tank. To duplicate the detritus tank and increase its size considerably would be a very fair safeguard in a case of sudden storms, because you would get a large amount of solids which go into the stream now in a tank even of that size, though, of course, it would have to be very much larger to be of any real service. It need not be anything like a day's flow, for example. You would get from a comparatively small tank very good results, in my opinion, from the point of view of the stream.

20656. Then you do not think, do you, that it is preferable to call upon local authorities to deal with more than six volumes; but you think it is practicable to call upon them to deal with six?—Yes; I think so, spread over the twenty-four hours. And then, of course, you would have to have conditions with regard to short

periods of more than that being held back in certain districts for subsequent treatment.

20657. How do you mean spread over twenty-four hours?—That is to say, the mean daily flow.

20658. You would require that their sewers should be capable of bringiug six times the average dry weather flow to the works?—Yes; to the works.

20659. And that such volumes should be dealt with at the works; possibly not in the same way as the dry weather flow, but should be dealt with, at all events, to the extent of settling suspended matter?—Yes,

20660. In other words, you think that by this provisional requirement the Local Government Board have just?—Happened to hit off the quantity.

20661. Hit off what is practicable?—I think so.

20662. If not, what is wholly desirable?—I think so.

20663. Does any authority in your district in fact do this?—I shall just have to think for a moment. Oh, yes, we have several authorities doing that, but most of the authorities who do that now have artificial means of disposal up to three times, and then they have land for discharging the storm sewage on to, and where land is available I think that is a very excellent way of dealing with it.

20664. Then, however, it is dealt with; certain authorities in your district do in fact deal with six times?—Yes.

20665. And you gather, therefore, that it is practicable to deal with it?—Now, for instance, at the Birmingham works; what they are endeavouring to arrive at is artificial filters for the dry weather flow, retaining some 1,400 acres of land practically almost for storm water only.

20666. What is proposed at Hanley in regard to storm water?—They propose to have some storm filters at Hanley.

20667. But I mean as regards the volume to be dealt with?—They have nine acres.

20668. How many volumes of the dry water flow?—Six times; it is the same as the Local Government Board requires.

20669. Judging from that and what has been done by other authorities, you give us your opinion that it is practicable for authorities to do this?—Authorities can do this at a cost of about £1 to 25s. per head of the population for works; that is what I think is about the average price.

20670. Is there any point in connection with storm waters that you would like to mention to us upon which I have not asked you questions?—I should like to call your attention to the figures; in the table I have given you, "Rainfall as affecting the condition of certain streams in Staffordshire," they are of different character. For instance, the Fowlea brook is a stream which is of small volume, you will notice, and on that stream there is a very large population. Now the result of storm water in that case, from these figures, appears to be that it never reaches the stage at which dilution begins to purify again. If you notice taking the organic ammonia figure ·13 when the rain is under one-tenth inch; 1·5 when it is over one-tenth and under one-fourth inch; 2 when it is over one-fourth—the day before, that is. (The table referred to is printed at the end of Dr. Reid's evidence.)

20671. That does not mean that when the rainfall is in quantity, but the stream is very much larger in quantity than when there was only one-tenth?—Oh, yes, it means that very much so; it is not only larger in quantity, but the stream is very much larger in volume, so the amount of impurity which is added to that stream is enormous.

20672. I see; this is not a gauging of effluent from works, but the condition of the stream itself?—The condition of the stream itself.

20673. And that is so throughout the table?—That is so throughout the table, yes. That is with regard to Fowlea brook. Then if you take the Lyme brook. The Lyme brook is a comparatively small stream, but it rises in a rural district, and there is a considerable rural as well as urban area draining to it, the result of that is that you get the impurity increased up to the quarter inch, but it begins to right itself again when you exceed the quarter inch. That is owing to surface, comparatively pure water going in. Now then take the Trent at Hanford, which may be said to be the sum of the other two streams practically plus the Trent. It is a small stream at that point, and the same thing takes place there again. After Hanley and all the big towns have gone in you get an impurity in the stream when the rainfall is under one-tenth of an inch—·09, it rises to 0·17, with quarter of an inch, and then begins to fall again when the dilution exceeds the quarter inch. But take the Tame at Tamworth, which is about the worst instance of pollution, I think, that you could have in the country. Here the volume of the stream and the volume of the sewage entering it are about equal, and we have an impurity figure of 0·1 with under one-tenth of an inch rainfall, and the same up to one-quarter inch. As, however, the rain records in this case are not very numerous we must not draw too hard and fast conclusions from them, but if you notice the next figure, 0·19, there is a very great increase, and that is 20 miles below the outfall.

Dr, George Reid.

9 Dec. 1904.

20674. That means that a great deal of untreated sewage passes by the storm overflows to the stream?—Yes. Then this stream has been diluted by other feeding streams going into it, so if we take the same streams higher up in the supplementary table below, that is immediately below the Birmingham works, immediately below where the sewage of nearly one million people goes into it, the impurity figure there when the rainfall is under one-fourth 0·18, and it rises up to 0·32, a most horrible condition of things, worse than many sewages when the storm overflows come into play. On the other hand, the Churnet is a pure stream, comparatively, and the normal conditions there are 0·019 organic ammonia, and by inflow from agricultural land the figure is raised to 0·03, and it appears to be maintained at 0·03, no matter how much the rainfall increases, so that you might look upon that as the normal increase of impurity from agricultural land in an ordinary district.

20675. And the table goes to show that it is in the abstract very desirable to treat as much storm water as possible?—Yes; and I think in the case of Birmingham the reason for this enormous impurity is the character of the sewers. They are old sewers; they are largely sewers of deposit, and are practically cesspools being periodically emptied, when the rainfall comes, and the remedy, of course, for that is very largely resewering Birmingham But after that they will have to come to a determination as to how much storm water they will deal with. There are many other points in connection with these figures, and there are other points taking further figures than the organic ammonia, but as it was I took three full days to work out these figures with two clerks at work upon them from my records. I could not therefore give any further figure than the organic ammonia, but all the figures are available. In these records—not only these but thousands of others—the full analysis has been made; they are all recorded and available for any inquiry the Commission may make.

20676. No doubt the organic ammonia would be a very good measure of the impurity of the stream?—The best single measure.

20677. We are very much obliged to you for coming over to give your most valuable evidence?—May I just mention there is a question with regard to the presence of weirs on streams. It has a very important bearing upon the question of storm water. In flat districts, and very often throughout Staffordshire, there are weirs—old weirs—and the result of that is that the rivers, flat in any case, are back pounded, and we get an enormous collection of sludge forming behind the weirs. The result, of course, of that is that when a little rainfall comes it is all washed down—not all, but a large portion is washed down, and of course the scouring capacity of the streams are diminished. Now, no central authority has power at the present moment to remove weirs from streams. Local authorities can get the power, but then if they do so, they are benefiting an area outside their own area in many cases, so that I think there ought to be some central authority who should have the power of purchasing mill rights for the purpose of abolishing weirs. We have had several abolished already with very excellent results, and such powers would get over a considerable difficulty in our county where the streams are so very small. The Trent rises in Staffordshire by mere trickles, and immediately it forms a little bit of a stream all these vast populations turn their sewage into it, so that we have a very difficult problem in

Dr. George Reid.

9 Dec. 1904.

Staffordshire, and it is complicated by the existence of a great many weirs.

20678. Then you have, in fact, many derelict weirs?—Yes; well, we have not many, but we have several, and they are on the main streams; consequently, the position is serious.

20679. (*Secretary.*) When you say the central authority should have power to buy them you mean the county authority?—The county authority.

20680. Not a Government authority?—No, the county authority, with power to rate the area benefited.

20681-2. A Rivers Board, if there was one, or a County Council, if there was not one.—To rate the authorities whose districts are to benefit by this.

20683. (*Dr. Houston.*) I have been reading this table with great interest. I gather that, as a rule, the water during storms in these rivers is more impure per unit of volume, although it is of much greater volume?—Yes.

20684. Have you formed any idea how you could set the one against the other, the increase of total volume against the increase of impurity per unit of volume, so far as contaminating liquids going in are concerned? You see what I mean, do you not?—That is to say, to gauge the quantity going in.

20685. Yes, because it is commonly asserted that during the flood time it is quite proper to discharge impure effluents into streams?—Yes.

20686. I do not think we have had much evidence on that point?—I have done that in connection with an inquiry in my district, and I had all the streams gauged for a certain number of months; accurately gauged by fixed weirs, as nearly accurate as possible; and having got a record of the actual flow of each tributary then I was able to attach the responsibility for impurity to certain localities. That is to say, the impurity figure of a certain stream would be a very high one, but the flow of that stream was a very low one. On the other hand, another stream coming in, the impurity figure might be a lower one, but the volume of flow was considerably higher. Therefore, the injury was greater; so, taking all these from the top points, and then taking the lower figure when they have all gone in, I have built up a table—at least, a diagram—showing the actual building up of the total impurity at the bottom, based upon the figures that you have just mentioned. I think that is what you mean, is it not?

20687. Yes; quite?—I have done that with regard to practically the whole of South Staffordshire. That was practically after an inquiry of two years' duration, and in consequence of the evidence certain authorities have spent some £500,000 in works, and are going to spend about the same sum more, I think.

20688. Might I venture to ask you to ask Dr. Reid if he could let us have these figures; they are very interesting.

20689. (*Chairman.*) Would it be possible for you to give us those?—Well, there are reasons, which the Commission will appreciate, for not making the records public, but no doubt I could collate them in a manner which would answer the purpose, without going into detail, regarding the authorities interested, and I shall be pleased to do so.

TABLE handed in by Dr. REID.

SEVENTY-SECOND DAY.

Tuesday, May 9th, 1905.

PRESENT:

The Right Honourable Earl of Iddesleigh (*Chairman*) presiding.
Major-General Constantine Phipps Carey, C.B., R.E.
Colonel T. W. Harding, J.P., D.L.
Sir William Ramsay, K.C.B., F.R.S.
Mr. W. H. Power, C.B., F.R.S.
Mr. T. J. Stafford, F.R.C.S.I.
and Mr. F. J. Willis (*Secretary*).

ALSO PRESENT:

Dr. A. C. Houston.
Dr. George McGowan.
Mr. G. B. Kershaw.
Mr. C. C. Frye.

Mr. G. H Pickles, A.M.I.C.E., Borough Engineer of Burnley, and Mr. Raymond Ross, F.I.C., F.C.S. Public Analyst, called in; and Examined.

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

20690. (*Chairman.*) You are Mr. Pickles, Associate Member of the Institute of Civil Engineers and Borough Engineer of Burnley?—(*Mr. Pickles.*) Yes.

20691. And you are Mr. Raymond Ross, Fellow of the Institute of Chemistry, and Fellow of the Chemical Society, and Public Analyst of Burnley?—(*Mr. Ross.*) Yes.

20692. The evidence which is to be given by both of you relates more particularly to your experience in the treatment of sewage at the Burnley Corporation sewage works?—Yes.

20693. What is the population draining to the Burnley works?—There are two outfalls, one for the Wood End and Duck-Pits area, the other for the Altham area. Our evidence is with regard to the Wood End and Duck-Pits works. The total population draining to these works is 82,000.

20694. What is the system of drainage, that is to say, is the storm water either wholly or partially drained into a separate system, and if only partially, to what extent?—The area of the watershed is 2,800 acres, of which 1,012 acres are built upon. Of these 1,012 acres, 544 are sewered, the storm water being discharged into the sewer. The remaining 468 acres are provided with a system of surface water drainage in addition to the sewers.

20695. Is there any infiltration of subsoil water into the sewers?—Practically none.

20696. What is the water supply per head, and from what source does it come?—The water consumption for domestic purposes is 21.27 gallons per head, and for manufacturing purposes, 3.90 gallons per head; total, 25.17 gallons per head. The water is obtained from a moorland gathering ground, augmented by springs. The water is impounded in reservoirs.

20697. Is it hard or soft water?—The water is very soft. The hardest of the supplies is as follows: temporary hardness, 3.0 parts per 100,000; permanent hardness, 3.0 parts per 100,000.

20698. What is the drainage area of the part of the town which is sewered?—1,012 acres.

20699. What proportion of the population use pail closets or middens and what proportion use water-closets?—97 per cent. use clean water or waste-water closets; 3 per cent. use tank or pail closets.

10700. Has the flow of sewage to your works been gauged? If so, what is the average number of gallons delivered at the works per day of 24 hours in dry weather in winter and in summer?—It has been found impossible to gauge the flow of sewage continually by means of an automatic recording gauge, as the levels would not permit of this being fixed satisfactorily. The flow of sewage has, however, on various occasions been calculated from the depth and velocity in the brick conduits. The results were as follows:—Dry weather flow: Winter, 2,500,000 gallons; summer, 2,000,000 gallons.

20701. What is the maximum dry weather rate of flow, and at what hour does this occur?—At the rate of 4,320,000 gallons per 24 hours between the hours of 12 and 2 and 3 and 5 p.m.

20702. What is the minimum dry weather rate of flow, and at what hour does this occur?—750,000 gallons per 24 hours between 2 and 4 a.m.

20703. What is the maximum wet weather rate of flow which you have observed coming to the works, and during how many hours has this continued?—About 9,000,000 gallons per 24 hours. This rate of flow has been known to continue for more than 24 hours.

20704. What storm overflows have you on your sewers, and at what rate or rates of flow do they come into operation?—There are 36 storm overflows on our system of sewers. Of these only three are on the main outfall sewer. The others discharge into streams at different parts of the town, and there are considerable variations in the number of dilutions at which they come into operation. Most of these are, however, connected with the smaller sewers, and it is intended to do away with them gradually as the sewerage system is amended. The maximum and minimum rates of flow on the various branch sewers have not been determined.

20705. What is the largest number of gallons of sewage which has passed the last storm overflow and come to your works in 24 hours?—9,000,000 gallons.

20706. Can you say what is the volume of water in gallons represented by the average yearly rainfall on the drainage area?—Yes; it is 2,541,500,000 gallons per year = 6,963,014 gallons per day.

20707. Can you give the Commission an approximate statement as to the volume of sewage which comes to your works during the year, and the volume which passes over your storm overflows?—The volume which comes to the works is approximately 2,000,000,000 gallons. We are unable to make an estimate as to the volume which passes over the storm overflows.

20708. How many gallons of trade effluent enter the sewers daily (24 hours), and what is the nature of these effluents? If you have analytical figures, please give them?—The principal trade effluents going to the Duck-pits works consist of:

Dye effluents - - - - - - - 4,000 gallons per day.
Tannery - - - - - - - - 10,000 „ „ „
Gasworks - - - - - - - - 6,000 „ „ „ for 8 months of year.

The Analyses of these Effluents are as follows :—

	Organic Matter.	Mineral Matter.	
Tannery effluent :			
Suspended matter	308·0	16·0	
Solids in solution	206·0	50·0	
Total solids			580·0
Tannery effluent :			
Suspended matter	43·2	36·8	
Solids in solution	26·8	57·2	
Total solids			164·0
Dye and cleaning effluent :			
Suspended matter	36·0	21·6	
Solids in solution	54·0	62·0	
Total solids			173·6
Dye and cleaning effluent :			
Suspended matter	53·0	53·0	
Solids in solution	320·0	868·0	
Total solids			1294 0

20709. Has your authority framed any rules as to the reception of trade effluents into sewers?—When connections are made to the sewers the Corporation do not permit trade effluent to be discharged, except by special arrangement.

20710. Do you find trade effluents interfere with the process of purification by reason of their quality, variations in composition, fluctuations of volume or otherwise? If so, would you kindly tell us what your difficulties are?—The only trouble we have had with trade effluents has been at the Altham Works, where the dry weather flow is only 350,000 gallons per day, and where 250,000 gallons of very concentrated dye effluent are often discharged per week. This effluent has for a considerable number of years been held up in one or two tanks (each having a capacity of 100,000 gallons) and run off as each tank was filled. During dry weather trouble was often caused by the excessive amount of dye effluent delivered at the works during a short period of time. The oxygen absorption figure in the final effluent was very greatly increased. Recently the effluent has been run through both the afore-mentioned tanks (as sedimentation tanks), thus arresting large quantities of gelatinous material, and the effluent has continuously run into the sewers. Since this alteration has been in vogue no trouble has been experienced in obtaining efficient purification.

20711. In dry weather what is the average amount of suspended matter in the sewage, and what are the highest and lowest figures, in parts per 100,000?—The average amount of suspended matter in dry weather is 119; the maximum is 186, and the minimum 83 parts per 100,000.

20712. What is the physical character of these solids?—On wet sample: Moisture, 79·31 per cent.; organic matter, 16·14 per cent.; mineral matter, 4·55 per cent. On dry sample: Organic matter, 78 per cent.; mineral matter, 22 per cent.

20713. Can you give us average analyses of the sewage for the years 1903 and 1904 in summer and in winter?—Yes; the average analyses are as follows :—

	Free Ammonia.	Albuminoid Ammonia.	Chlorine.	Oxygen Absorbed.
1903 Summer	2·733	·889	11·1	7·907
„ Winter	2·062	·659	9·3	8·408
1904 Summer	5·753	1·230	11·7	10·466
„ Winter	2·748	1·114	11·4	13·167

20714. Is it a "strong" sewage, and, if so, what characterises its strength?—The sewage is a strong domestic sewage with high albuminoid nitrogen and oxygen absorbed figures. This is largely due to the great number of waste-water closets in use in the Borough.

20715. Does its strength vary very much from hour to hour or on different days of the week, and, if so, do these variations affect the quality of your final effluent to a marked degree?—It is subject to considerable variations in strength, but the tank accommodation is so large that these variations do not affect the quality of our final effluents to any marked degree. The question is answered on the assumption that it refers to a normal weather flow.

20716. How do you think "strength" of sewage as affecting purification is best expressed or measured?—By a full analysis, including the amounts of free and organic nitrogen, suspended matter (organic and inorganic), dissolved solids (organic and inorganic), cellulose, and grease; the three minutes oxygen test as an indication of trade effluents; germicides.

20717. Have you any information as to the bacteriological condition of the sewage in dry weather and in

Mr. G H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May, 1905.

storm times?—Only as regards the total number of bacteria present. These vary from about 24 millions per c.c. in dry weather flow to as low as four millions per c.c. during continuous wet weather.

20718. Are there any chemical poisons in the sewage?—There are no chemical poisons in our sewage.

20719. Is the sewage always alkaline?—Yes, except when considerable quantities of dye effluent are being delivered at the works.

20720. Do you find that the amounts of suspended solids are increased or diminished in times of storm; and can you give the Commission the figures at the end of each hour during a storm of some hours' duration?—The amount of suspended matter is first increased and afterwards diminishes rapidly. The following figures were obtained during a storm of four hours' duration, the samples being taken between the hours of 1 a.m. and 5 a.m.:—

Average sample during	Suspended matter.
1st hour	24·8
2nd ,,	80·0
3rd ,,	25·6
4th ,,	5·6

20721. How many years ago were your sewers laid, and do you know whether they have sunk much in places so as to allow solids to accumulate?—The present main outfall sewer was constructed in 1873, but a great proportion of the sewerage of the Borough has been dealt with since that date, and it is being added to each year. There are no sunk places in the sewers.

20722. What is the character of the liquid part of the sewage in storm times? Perhaps you could illustrate this by analyses of the liquid portion in dry weather and in storm times?—Its character is shown by the following analyses:—

During Storm Time.

—	Crude sewage.	Crude sewage after filtration through paper.
Free ammonia - -	1·200	1·200
Albuminoid ammonia -	·640	0·320
Oxygen absorbed in 4 hours at 27° C. - -	10·784	6·708
Total solids - - -	116·0	76·8

During Dry Weather.

—	Crude Sewage.	Crude sewage after filtration through paper.
Free ammonia - -	5·000	4·500
Albuminoid ammonia -	1·760	·960
Oxygen absorbed 4 hours - - - -	21·000	9·750
Total solids - - - -	218·4	98·0

20723. In what way or ways do you think the sewage which comes to the works should be dealt with in storm times? Perhaps I should amplify this question a little. The usual requirements of the Local Government Board are, I understand, that any increase in flow up to three times the normal dry weather rate should be fully dealt with by the ordinary complete plant, and that a certain number of additional dilutions—up to a total of six—should be treated on special storm filters. Do you think these are proper requirements, or do you think they should be modified in any way? It is, I believe, often found that the storm sewage which first comes down to the works contains a largely-increased amount of suspended solids, and I should like to know whether you consider that your ordinary (dry weather) plant is exposed to damage in any way—as, *e.g.*, rapid choking—by having to deal with this amount of storm sewage, and whether you think it would be better to adopt some other treatment. Although the storm sewage, including the suspended solids, is a very polluting liquid, possibly the liquid portion alone is not very polluting, and this suggests that settlement of all the sewage arriving at the works in time of storms in tanks for a few hours, after, possibly, the addition of chemicals, might perhaps be a better plan of treatment than passing a portion of it through the ordinary plant, and the balance through storm filters. Would such settlement alone be sufficient for the whole of the sewage arriving at the works in times of storm?—We think that the regulations of the Local Government Board might with advantage be modified to some extent. We quite agree that three times the dry weather flow should be purified on contact beds after passing through the septic tanks. During times of storm, when the flow is greatly increased above this amount, in our opinion it would be better to continue to run through the septic tanks till the streets had been thoroughly washed and the polluted storm water had arrived at the works, after which the remaining portion of the diluted sewage should be passed through detritus tanks and treated on storm beds. A flow equal to the normal dry weather flow should be run during this period through the tanks to prevent the possibility of over-septicism. As we do not advocate, partly on the ground of expense, a tank accommodation greater than 24 hours' dry weather flow, to run more than three times the dry weather flow through the tanks for any time would cause a great increase in the amount of suspended solids of the tank effluent, to the detriment of the contact beds. A method we have found very advantageous in dealing with moderate amounts of storm water is to hold up the storm water on land areas to the depth of about one foot. These areas are in a sequence of three or four, and the settled effluent from the last area is run over a scum board into a storm bed, where it is held in contact for about two hours. When necessary these storm beds can be filled as often as four times a day.

20724. What shape and size are your storm overflows?—In most cases the storm overflows have fixed sills, but in some instances leap weirs have been adopted. The sizes of the overflows are such that the sewers are prevented from being put under pressure during storm times.

20725. Would it be possible to have a standard form of overflow; and how would you fix the point at which overflows should be allowed to come into operation?—We think that overflows should have fixed sills, but in some cases we think it would be advisable to adopt leap weirs, the sills of the leaps being immovable and fixed according to circumstances.

20726. Do you think that the point at which storm overflows should come into operation should depend on the configuration of the land, and upon the character of the surface soil geologically?—We do not think that it is necessary to consider the configuration of the land if the storm overflows are fixed at six dilutions, because whether the land be hilly or flat, the street washings would be delivered at the works before the flow in the sewer reached the six dilutions. The same remarks apply to the surface of the soil geologically.

20727. Should storm overflows be fixed or movable?—We prefer that the sills of the storm overflows should be fixed, but that they should be capable of being raised should an increase in the dry weather flow necessitate the same.

20728. Do you think the number of dilutions at which storm sewage may properly be allowed to pass into the stream should be dependent upon the size and nature of the stream into which the storm sewage would pass? Is it possible, for example, that in some circumstances no injury to the stream would be caused by allowing overflows to come into operation when the increased flow was slight, while in others this would not be the case?—We think that in fixing the number of dilutions at which storm sewage may be passed into the stream, the size and nature of the stream should be considered specially with reference to the rate of increase in the volume of the stream and its velocity during storm

times. It is possible, under certain conditions, where the volume of the stream is very great in proportion to that of the sewage, that once the road washings have been disposed of the whole volume of the storm sewage might be discharged into the stream without detriment to it.

20729. If your town is drained on the separate system, what happens to the road water?—The surface water which falls on the front streets and front parts of the houses is drained into the surface water drains which discharge into the stream or the canal at convenient points. That falling on the back streets and the rear portions of the houses is drained into the sewers; the portions thus dealt with are practically equal in area.

20730. Could you give us an analysis of a typical sample of your road water during the early period of a storm?—Yes; the analysis gives:—

Free ammonia	·800
Alb. ammonia	·200
Chlorine	4·0
Oxygen absorbed	5·300
Total solids	71·2
Containing suspended matter	44·0

20731. Have you any information as to the bacteriological condition of the road water?—The above sample contained about 800,000 bacteria per C.C., as shown by gelatine plate cultivation at 20° C.

20732. Do you consider that in certain circumstances this liquid should be purified?—We think it desirable that when possible the first portions of the storm water should be purified, unless the size and volume of the river is such as to render it unnecessary.

20733. What are your views as to the comparative cost and advantages of the separate and combined systems of sewers? Initial outlay as well as annual cost should be borne in mind?—Irrespective of the question of cost, but from a sanitary point of view, we consider that it is necessary that some portion of the rain water should be discharged into the sewers. If the sewers are made sufficiently large to take all the rain water in addition to the normal quantity of sewage, the scouring action during dry weather would be quite insufficient. Further, in hilly districts, where the streets are paved, the surface water collects so rapidly that flooding would ensue in the lower parts of the town unless the drains were abnormally large. As regards the question of cost, in our case, a partially separate system has cost about one-fifth more than if we had constructed a combined system alone. This cost would, of course, vary with the system of drainage adopted. The annual cost of maintenance of surface drains is very small compared with that of the sewerage system. In our case the surface water drains discharge at numerous convenient points into the rivers. The fact that the first washings of the streets discharge into the streams is of course a disadvantage, but in a hilly district like ours the increase in the volume of the stream is so rapid that no nuisance is observable. From these considerations we are of opinion that in most circumstances a partially separate system of sewers is desirable.

20734. Have you had experience of the chemical precipitation of sewage?—From 1893 to 1899 chemical precipitation was adopted, the precipitants being lime and copperas. In 1900 the tanks were converted to the septic system, which has been continued ever since.

20735. Have you any reason to think that sewage from which the solids have been removed by the aid of chemicals is less easily purified by subsequent filtration than sewage from which the solids have been removed by settlement or by passage through septic tanks?—When sewage precipitated by lime and copperas was treated on contact beds we obtained fairly good results, but we think that better results were obtained by doing away with precipitants and using septic tanks effluents.

20736. Have you tried various chemicals; and can you give any comparative data on the practical value and cost of different precipitants?—Our experience with chemicals other than lime and copperas has been too slight to be of any value.

20737. What was the average analysis of the liquor from your precipitation tanks? What length of time did the sewage remain in the tanks?—The average of four months' analyses is as follows:—

Albuminoid Ammonia	0·972
Oxygen absorbed in 4 hours at 27° C.	7·714

There was about a 12 hours' dry weather flow through the tanks.

20738. Did you find it necessary to add further chemicals to the sludge before it could be dealt with?—It was found necessary to add a certain quantity of milk of lime.

20739. What was the manurial value of the sludge obtained by the chemical precipitation of sewage, and would farmers take it?—The manurial value was principally due to the amount of lime present. It came out at a valuation of about 1s. 2d. per ton for the pressed cake. There was a fair demand for this manure, which was sold at 10d. per ton.

20740. Did it contain any chemical poisons?—No.

20740*. Did you find any nuisance from the treatment of sewage in chemical precipitation tanks? Were any complaints made?—No nuisance was caused and no complaints were made.

20741. As regards septic tanks, what shape should they be?—We have found the rectangular shaped tanks 80 ft. by 46 ft. by 6 ft. 6 in. deep convenient in shape and size for our flow of sewage.

20742. Should they be divided into sections?—We do not know of any advantage to be gained by dividing tanks into sections.

20743. Should they be used in series or in parallel?—This question is to some extent under consideration. At present we are using the first ten tanks, equal to about 9·6 hours' dry weather flow, in parallel, and the effluent from these tanks is then passed through seven other tanks (14·4 hours' capacity), also worked in parallel. It is intended to work all the tanks in parallel at some future time, with a view to ascertaining whether this or the before-mentioned method is the more satisfactory.

20744. Is a scum necessary or desirable?—A scum is, we believe, desirable, although at times when many of the tanks have been without one we have not found any difference in the purity of our final effluents.

20745. Should the septic tank be closed in, and, if so, what advantages does a closed tank possess over an open one?—We have experimented with a concrete covered septic tank and an uncovered septic tank of exactly similar dimensions. The results obtained prove conclusively that with our sewage nothing was gained by covering the septic tank.

20746. What do you consider the best arrangement for the "feed" and "draw-off"?—We have found that the best method is to admit the requisite quantity of sewage at the deep end of the tank by means of sealed inlets so arranged as to give the greatest possible diffusion throughout the tank. The draw-off consists of a sealed outlet and sill running the whole length of the end of the tank opposite to the feed.

20747. At what rate is sewage, as a matter of custom, passed through your septic tanks?—The average flow of sewage through our tanks is about four million gallons per 24 hours, equal to 15 hours' septic digestion.

20748. What is the most advantageous rate of flow through septic tanks, and what is the rate of flow at which quicker passage through the tanks becomes, in your opinion, distinctly disadvantageous?—The average rate of flow through our tanks is as follows:—Maximum flow of which the duration is six hours at the rate of 6,000,000 gallons per 24 hours or 10 hours' digestion. For the remaining 18 hours of the day, the average of the rate of flow per 24 hours is 3,333,333 gallons, or a digestion of 18 hours. From experiments which we have made there does not appear to be much difference in the effluent between 12 and 24 hours' digestion, and we have attempted to keep our sewage as nearly as possible within these limits. If the flow is too rapid the suspended matter in the effluent is greatly increased, and we see no advantage in more than 24 hours' contact.

20749. Is it possible to "over-septicise" a sewage, and, if so, for what reasons, and how is the "over-

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

septicising" brought about?—We have not had in practice any specific instance of over-septicism. It is, however, undoubtedly a fact that if sewage is kept too long in the tanks considerable quantities of sulphuretted hydrogen would be produced, not only causing a nuisance, but interfering with the subsequent treatment of the effluent, by using up oxygen for its oxidation and by interfering with hydrolysis.

20750. What is the amount of digestion in your septic tanks? How far do you find that the digestion is affected by the atmospheric temperature?—We regret that we have not had the means at our disposal to estimate this figure ; slight variations in temperature make no difference, as, although the average temperature in the closed septic tank was somewhat higher than that in the open septic tank (during a period of six months), the amount of sludge formed in each case was practically identical.

20750. Do you think a certain amount of sludge should be removed periodically from septic tanks, or do you prefer to work them for a considerable period without cleaning, and then remove all the sludge?—We prefer to remove our sludge entirely at fairly long intervals, because the greater part of it accumulates at the surface of the tanks.

20752. How often, then, would you clean out the tanks?—The septic tanks are entirely cleaned out every six months.

20753. How do you think the sludge should be taken out of the tank, and how should it be disposed of? Does any nuisance attend the operation?—Our practice is as follows:—The liquid portion of the contents of the tank which is to be sludged having been run off, sewage is run on to the settled scum, which is then broken up by means of long wooden rakes. The resultant sludge is then pumped into an adjoining tank which is kept empty for the purpose, milk of lime being added to the sludge at a point adjacent to the inlet of the tank, thus ensuring a thorough admixture of lime and sludge. The sludge is then allowed to settle for about 12 hours, after which the supernatant liquid is drained off. A further quantity of milk of lime is then added to the sludge, after which the whole is pumped into an adjoining sludge tank and pressed in the usual way. The total quantity of lime used for pressing is about 5 per cent. of the wet sludge or 20 per cent. of the pressed cake. For the intermediate tank, it has been found convenient to use whichever of the detritus tanks happens at that time to have been pumped clear of detritus sludge. Owing to the thorough admixture of lime and sludge, no difficulty has been experienced in pressing the septic sludge.

20754. Do you find that the suspended solids coming away with the tank liquors tend to increase in amount towards the end of the period of working—*i.e.*, as the time approaches for removing sludge from the tank?—Yes, we have found this to be the case.

20755. What amounts of suspended solids, stated in parts per 100,000, are contained in your septic tank liquor at the commencement of the period of working the tank, *i.e.*, just after the tank has been cleaned out, and at the end of period, *i.e.*, when the tank is thrown out of use for the purpose of cleaning out, and what is the average amount?—We have not been working a sufficient time with our full number of tanks to be able to give the required data. With the original 10 tanks (capacity about 10 hrs. dry weather flow) the suspended matter in the tank effluent varied from about 15 parts per 100,000 after a few weeks' working to 35 parts per 100,000 at the end of six months. During the last four months this effluent has passed through four additional tanks (which will shortly be increased to seven), and the suspended matter during times of normal flow has varied between three and seven parts per 100,000.

20756. Should any portion or the whole of the sewage which arrives at the outfall works in storm times be passed through the septic tanks?—We think that up to three dilutions the sewage should be run through the septic tanks, and after this only until the polluted storm water has been delivered at the works. When this has taken place, a flow about equal to the normal should be allowed to continue to run through the tanks.

20757. If storm sewage is passed through a septic tank, does this cause an increase in the amount of suspended solids issuing from the tank, and, if so, can you give us figures showing what the increase is?—During the storm referred to in Question 20720 the whole of the storm sewage was passed through the tanks, and samples taken each hour, with the following results:—

	Suspended Solids.
1st hour - - - -	4·0 parts per 100,000
2nd ,, - - - -	8·0 ,, ,,
3rd ,, - - - -	8·0 ,, ,,
4th ,, - - - -	9·6 ,, ,,

20758. May you admit storm sewage to your septic tank, to an extent which raises the ordinary level of the liquid, without serious detriment to the functions of the tank?—As the levels of our tanks can only vary within very small limits we cannot give any information on this point.

20759. With certain automatic gear the level of the liquid in a septic tank fluctuates. Have you made any observations for the purpose of determining whether such fluctuations disturb the proper working of the tank in any way, as, *e.g.*, by causing an increased amount of suspended solids to issue from the tank?—We have never used any automatic gear.

20760. Do you find that septic tank liquor is more easily treated on filters than settled sewage or than precipitated sewage, assuming that in each case you have the same amount of suspended solids in your tank liquor?—We obtained better results with septic tank effluent than with chemically treated effluent.

20761. Are the impurities in solution in sewage materially different from the impurities in solution in septic tank liquor?—We have not carried out sufficient work on this subject to make our evidence of any real value. It is undoubtedly very complicated, owing to the action of the sludge and the alteration of the constitution of the dissolved solids.

20762. Have you any data on the relative value of plain septic tanks, and septic tanks filled with rough stones or flints?—No.

20763. Do you find any nuisance from the treatment of sewage in septic tanks? Have any complaints been made?—We have never experienced any nuisance, nor have any complaints been made.

20764. Do you think it desirable that the suspended solids in sewage should be removed as far as practicable before sewage is filtered? If so, what do you consider a practicable limit to get down to?—We think that it is desirable to remove the solids as far as possible. In our case we get down to between five and six parts of suspended matter per 100,000. When we had only half the number of tanks the suspended matter was very much higher.

20765. How do you consider that the removal of suspended solids can best be effected?—Firstly, by screening to eliminate the coarser material ; and, secondly, by means of large detritus tanks ; then by means of septic tanks of at least 24 hours' dry weather flow capacity.

20766. Have you any experience of any mechanical device or any special tanks for freeing tank liquor of suspended matter before delivering it to filters?—No.

20767. What other (if any) method of dealing with tank liquor before delivering it to filters do you regard as necessary or advisable?—We have not found any additional method necessary, but the distributing troughs on the contact beds arrest a considerable amount of suspended matter.

20768. May I ask you to put before the Commission a full statement of your views as to the comparative cost and relative advantages of the various methods of settlement? I am not sure whether it would be possible for you to make this comparison on the assumption *that in each case you reduce the same sewage down to the same figure for suspended solids*, but if this could be done it would be useful to include a comparison on this basis?—The comparative costs in our case were as follow:—The initial expenses were about the same for both methods of treatment. We cannot speak as to the suspended solids, because we have no figures showing the amount of the suspended matter in the chemical precipitation effluent, but judging from the appearance it was only slight. The following statement does not include any payments in respect of principal or interest

on loans, but only the actual annual working expenses:—

	Chemical Precipitation.	Septic Tanks.
	£ s. d.	£ s. d.
Lime precipitation and pressing	742 0 9	346 17 8
Copperas	96 15 4	—
Coal	253 10 3	185 5 8
Press cloths	155 0 0	113 2 8
Wages	683 16 0	485 17 0
	1,931 2 4	1,131 3 0
Less receipts for manure	317 12 0	150 4 0
	1,613 10 4	980 19 0
Cost of treatment per million gallons of dry-weather flow	£2 4 2	£1 6 8

When we were using precipitants we got more than twice the amount of sludge that we do at the present time from the septic tanks. The pressed cake produced during the time of chemical precipitation averaged about 7,500 tons per annum. By the present system of working we obtain:—

2,795 tons of pressed septic sludge cake per annum.
8.0 „ „ detritus „ „ „

Total 3,605

The purification from the chemical effluent was not quite so satisfactory on contact beds, and considerable quantities of hydrated oxide of iron were deposited in the bed. It is quite conceivable that with certain kinds of trade effluents some method of precipitation has to be resorted to, though we have had no practical experience of this.

20769. As regards contact beds, is it advisable to construct the whole or any part of the interior of building materials, or may you in some cases dispense with this entirely?—We consider that where the subsoil is of a heavy character all building materials may be satisfactorily dispensed with, except for the construction of the outlet chamber.

20770. Do you find that within certain limits the depth of contact beds may vary without affecting their efficiency? If so, what limits do you think are permissible?—Although we have no personal experience with beds of a greater depth than three feet, we think that if increased much beyond this limit solidification of the lower stratum would take place, and the drainage of the bed would be interfered with. The aeration would also be less perfect, and the capacity of the bed would probably diminish more rapidly.

20771. What do you consider is the most convenient size for a contact bed?—The size of each bed should be such that it can be filled by the available flow of tank effluent in about two hours.

20772. What do you find to be the best filtering materials? What is the material (which can be had in practicable quantity) that, while efficient, is in your experience the least disintegrable in a contact bed?—We prefer to use hard-burnt clinker to any other material.

20773. What size should the filtering material be, and should it be graded in the beds?—We consider it necessary that all material used in the construction of contact beds should be both washed and screened. For the first contact beds, we use all material which is retained by a screen of half-inch mesh. Any large lumps are first broken, as they interfere with the screening machinery. For the second contact beds, the material passing through a half-inch mesh and retained by a ⅛in. mesh is used. No attempt is made to grade the material in the bed, but in filling the material into the bed the coarser clinker inclines to accumulate in the lower portions of the bed.

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

20774. How should the bottom of the bed be constructed?—The bottom of the bed should be excavated so as to allow of a good fall towards the outlet chamber. The drains are laid on the surface of the ground in herring-bone fashion, the under side of the pipes being laid in a grip. We have found it desirable to use glazed and socketed earthenware pipes with half-inch holes three-quarters of the way round the pipe. The main drain is laid with a fall of 1 in 200 towards the outlet chamber, and the branch drains have an inclination of 1 in 600. In secondary beds unglazed field tiles with butt joints have been used with satisfactory results.

20775. Do you think it generally desirable that sewage should be subjected to some form of tank treatment before it is put on contact beds?—We believe that some form of tank treatment is requisite.

20776. What periods of filling, standing full, emptying, and standing empty do you consider best in practical working for primary beds and for secondary beds?—With our sewage we have found for both the primary and secondary beds a period of about two hours' filling followed by a two hours' contact to be most satisfactory. We work two cycles per day, the beds standing empty not less than two hours between fillings.

20777. How should contact beds be filled and emptied?—We think that the most important point to be considered in filling a bed is perfect distribution combined with moderate aeration of the inflowing liquor. This we have obtained in a most satisfactory manner by means of troughs fixed 6ft. to 8ft. apart. The troughs are fixed on the surface of the bed, and can easily be re-adjusted in case of settlement. The effluent runs gently over the sides of the troughs which have no perforations. Facilities are provided for emptying and cleaning the troughs. In emptying a bed we open the outlet valve to its full extent, thus emptying the bed as quickly as posible.

20778. Have you had experience of automatic gear for filling and emptying contact beds?—We have not used any automatic apparatus for filling or discharging. The reasons which have led to the exclusion of automatic apparatus are as follows:—

(1) They are very liable to get out of order, and consequently it is necessary to have a man always on the watch to see that they are working properly. As the attendance of one man is all that is required at our works to control the valves, no saving of wages would be effected, but there would be a considerable increase in capital outlay, as all these appliances are expensive to instal, and we think costly to maintain.

(2) Automatic apparatus takes no notice of the condition of the bed, which, in our opinion, is a matter of considerable importance.

(3) Where the flow of sewage varies it is desirable to be able to bring the larger beds into use during the time of the greatest flow, so that their period of filling may approximately equal that of the smaller beds. This we consider is best accomplished by hand control.

20779. What amount of tank liquor per cubic yard of filtering material can, in practice, be properly treated in a primary contact bed in 24 hours? If the amount varies with the quality of the tank liquor, please state by analytical figures what quality you are assuming, and how differences in the tank liquor affect the amount that can be properly treated?—Assuming that the bed has been made in conformity with our former recommendations (*see* No. 20773), we can treat 90 gallons per cubic yard (with two fillings) per 24 hours. When the strength of the tank liquor falls below about ·400 parts per 100,000 of albuminoid ammonia and 7·000 parts per 100,000 of oxygen absorbed (in four hours) about 45 gallons more per cubic yard can be treated.

20780. What amount of liquid from a primary bed can, in practice, be properly treated on each cubic yard of filtering material of a secondary bed in 24 hours?—Taking a typical second contact bed which has been in operation for 5¼ years, we obtained a gauging of 45·5 gallons per cubic yard capacity, and there has been no difficulty in maintaining this. We can therefore treat 90 gallons per cubic yard per 24 hours with two fillings.

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

20781. Can these quantities be increased by more frequent filling and emptying in times of storm without impairing the efficiency of the beds or the quality of the effluents?—With our sewage we do not consider that we could advantageously fill the beds more than three times a day without impairing the quality of the effluent.

20782. Is one contact sufficient for the conversion of certain tank liquors into a satisfactory effluent?—We have had no experience of sewage that could be so treated.

20783. At what rate or rates do primary contact beds and secondary contact beds lose their water-holding capacity?—No. 5 first contact bed, made of washed and re-screened material, recommenced working on June 15th, 1904. The following table gives the numerous gaugings which have been made of the capacity of this bed :—

FIRST CONTACT BED No. 5.

Contents of bed, 3,081 cubic yards, 519,912 gallons

No. 18 first contact bed was formed of unscreened furnace clinker, and commenced working in January, 1898. For a period of about six months it was used without troughs, otherwise distribution has always been by means of wooden troughs.

* The bed completed six months continuous working at two fillings per day on this date.

The following gaugings have been taken :—

Date of Gauging.	Total Capacity in Gallons.	Percentage Capacity in Gallons. Empty Bed—100.	Capacity in Gallons per Cubic Yard.
June 13, 1899 - - - - -	108,255	25·6	43·0
September 25, 1900 - - - -	65,374	15·8	26·5
November 13, 1900 - - - -	69,800	16·8	28·3
October 10, 1902 - - - - -	61,300	14·7	24·8
March 20, 1905 - - - - -	56,786	13·7	23·04

20784. Is the loss of capacity in direct proportion to the volume treated and the amount of suspended solids contained in the liquid which is put into the bed or to the fineness or coarseness of the material of the bed, or on what does it depend?—The loss of capacity, in our opinion, is due to the following causes :—

(a) The formation of gelatinous matter on the surface and in the interstices of the material, but necessary for the purifying action of the bed.

(b) The non-destructible suspended matter carried into the bed.

(c) Disintegration of the clinker and the consolidation of this disintegrated material to a spongy mass. In our opinion this accounts almost entirely for all further loss in capacity after the bed has once arrived at maturity.

(d) The accumulation of irreducible humus gradually deposited from the sewage. The weathering or wasting of this material probably accounts for the increase in suspended matter occasionally noticed in contact bed effluents.

20785. Can the material of a clogged bed be washed, and, if so, how can this best be done, and at what cost per cubic yard?—Yes, without difficulty. We have washed several beds of over a half acre in area in the following manner An inclined rotary screen 10ft. by 4ft. is fixed at a suitable elevation and so constructed as to be easily capable of removal from bed to bed as required. The whole is arranged so as to admit of washing, grading, and screening the clinker as required The material excavated from the bed is tipped into a boot fed with tank effluent, and is raised therefrom by elevators to the screen. There it is washed and graded in the way explained in reply to Question No. 20773. The wash water is run into a large wooden trough, where most of the fine material settles. It is subsequently purified on land areas and secondary beds. The power is supplied by a portable engine. The total cost of the screening machinery and engine and shed was £280. This machinery is capable of dealing with 100 tons of material per day of nine hours. The cost of screening a bed of 0·65 acres was at the rate of 1s. per cubic yard of the capacity of the bed. This includes excavating, packing troughs, wheeling, screening and washing not only the material excavated but also the additional material required to take the place of the portion rejected, and filling the same into the bed. This cost, although inclusive of fuel, does not include any interest on capital outlay. The following tables show the quantities of the various grades of material obtained by screening the clinker from the bed (the material of which had been dry screened when the bed was first made), and also from the screening of new furnace clinker collected from mills :—

Material from the Old Bed.

Material above ½ in. used for first contact beds - - - - - - -	60 per cent.
Between ⅛ and ½ in. used for second contact beds - - - - - - -	30 ,, ,,
Below ⅛ in. rejected - - - - - -	10 ,, ,,

New Furnace Clinker.

Material above ½ in. used for first contact beds - - - - - - -	40 ,, ,,
Between ⅛ and ½ in. used for second beds	38 ,, ,,
Below ⅛ in. rejected - - - - -	22 ,, ,,

20786. How can the capacity of contact beds be best maintained?—

(1) By efficient drainage.

(2) By the use of material which will not disintegrate.

(3) By filling the beds quietly and evenly, and as far as possible preventing the entrance of suspended matter.

(4) By allowing judicious periods of rest during which time the bed should be allowed to drain thoroughly.

(5) By keeping the surface of the bed in good order so as to prevent flooding.

20787. What is the average analysis of your single contact effluent and your double contact effluent?—The average analyses are as follows :—

——	Albuminoid Ammonia.	Oxygen absorbed in 4 hours at 27° C.	Nitric Nitrogen.	Chlorine.
Primary Beds—				
1902 - - - -	0·244	1·893	0·166	7·5
1903 - - - -	0·264	2·498	0·227	7·9
Secondary Beds—				
1902 - - - -	0·089	0·757	1·068	7·7
1903 - - -	0·072	0·799	1·056	7·9

20788. What number of gallons of liquid are treated daily per cubic yard of filtering material in your first bed, and what number of gallons are treated daily per cubic yard of filtering material in the two filters?—The number of gallons we can treat daily per cubic yard is 90 for first contact beds (two fillings). The quantity treated daily per cubic yards of filtering material in the two beds by two fillings is 45 gallons.

20789. Do you find any chemical poisons in your effluent?—No.

20790. What is the average amount of suspended matter in the primary bed effluent and the secondary bed effluent? Does most of this suspended matter come out with the first flush or not?—In the primary bed effluent the suspended matter averages 3 to 4 parts per 100,000. Second contact bed effluent averages about 1

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

part per 100,000. The first flush of the second contact bed contains about 4 parts per 100,000. This rapidly diminishes.

20791. To what extent do you find that the organic matter of the suspended solids issuing in the effluent from a contact bed is different from the organic matter of the suspended solids going on to that bed?—We have made no comparisons.

20792. Is the first flush of effluent from either set of beds ever putrescible?—The first flush from our first contact bed is generally putrescible; that from the second contact beds practically never.

20793. Do you find that by increasing the number of fillings in storm times or other times, the amount of suspended solids is increased?—The suspended solids in the final effluent vary from 0·4 to a maximum of 2·8 parts per 100,000. Storm water does not seem to have any effect on the final effluent in this respect.

20794. May contact beds in time of storm be used as streaming filters without detriment to their customary efficiency?—We consider that this would be very detrimental to the subsequent working of the bed.

20795. What was the cost of your contact bed installation per acre, and how much liquid do you treat per acre per twenty-four hours in ordinary times and in storm times?—The cost per acre is £1,300. The amount treated by double contact on beds three feet deep is 217,800 gallons per acre.

20796. Have you made any experiments which throw light upon the action of contact beds when full and when resting?—No. At the same time, we believe it has been proved that certain growths within the bed have a very powerful affinity for oxygen.

20797. Have you made a study of the conditions of aeration of contact beds, and, if so, with what results?—We have found that we can only get satisfactory results when distribution is good and when moderate periods are allowed for the aeration of the bed.

20798. Do you find any nuisance from the treatment of sewage on contact beds? Have any complaints been made?—No nuisance is caused, nor have any complaints been made.

20799. Could you make a comparison of the cost and relative advantages of percolating filters and contact beds?—We have no personal experience in percolating filters, but from results supplied by Accrington, and published in Dr. Fowler's paper read before the Sanitary Congress at Glasgow (1904) the cost per million gallons, calculated on the dry weather flow, is £3 7s., the percentage improvement effected on the tank effluent being about 76. The cost per million gallons by our double contact system is £3 7s. 6d., the percentage improvement being 85 on the tank effluent. This has been calculated as follows :

Total expenditure - -	£2,866	8	0
Less receipts from manure and crops	400	8	6
Net cost - - - -	2,466	0	0

These figures do not include interest on capital outlay. Dry weather flow is 2,000,000 gallons.

20800. Can you say whether the chance of nuisance is any greater with one form of filter than with another?—We have had no personal experience in working percolating filters. The contact beds at our works have never caused any nuisance, although we have a strong sewage to deal with.

20801. You have not made any comparative observations as to the amount which can be satisfactorily purified by the two forms of filter?—No.

20802. Could you express an opinion as to how the number of gallons which can be treated would vary with variations in the strength of your tank liquor, and on what figure or figures you would rely for defining the "strength" of your tank liquor?—The strength of the tank effluent in reference to the number of fillings would be gauged by the volume of sewage arriving at the works as compared with the normal flow (*see* also No. 20779).

20803. Have you had any experience of storm water filters?—We do not use storm filters as streaming filters at present, but as single contact beds after the effluent has been settled on land areas. By this method we have been able to keep the effluents within the Ribble Joint Committee's standard (*i.e.*, 0·150 albuminoid ammonia).

20804. Do you consider storm water filters lose any of their efficiency by being used intermittently at long intervals?—We prefer to give our storm beds at least three fillings per week, as otherwise we find that they do not work satisfactorily.

20805. Have you any practical suggestions to make for disposing of sludges?—Sewage screenings in our case are dug into the land adjoining the works, which is owned by a market gardener. The quantity is not great, being about 250 tons per annum. As regards other kinds of sludge, the only way we have found at all practicable is to press all sludge, whether detritus, precipitation, or septic tank sludges, and to dispose of the cake thus made. This cake is mechanically disintegrated, so as to be ready for use by the farmers. At present we are able to sell all our cake at 10d. per ton at the works. When we used chemical precipitation, the amount of sludge being much greater, we were sometimes obliged to dispose of a portion of it by sending it by canal ten or twelve miles into the country. We consider that the only practical way for sludge to be dealt with by inland towns is by pressing : 90 per cent. of the moisture is thus disposed of, rendering the material much more suitable for any subsequent method of disposal. What this latter method should be must be decided by each town according to the circumstances.

20806. Do you find that some methods of disposing of sludge are more likely to cause nuisance than others?—The disposal of sludge by natural drying is in our opinion likely to cause a nuisance.

20805*. What, in your opinion, constitutes a good effluent?—We should consider that the following factors are requisite for a good effluent :—

(1) That it does not contain any appreciable quantity of suspended matter.

(2) That it is non-putrescible under ordinary climatic conditions.

(3) That it does not deposit any sediment on standing, even after admixture with aerated water.

(4) That it should contain sufficient dissolved oxygen for the support of fish life.

(5) That it should contain sufficient nitric nitrogen to meet the requirements of the organic matter still remaining in the effluent.

20807. Do you consider that the type of effluent from a contact bed is superior or inferior to the type of effluent from a percolating filter?—We are of the opinion that the contact bed effluent is superior to that from a percolating filter, for the following reasons :—

(1) It is not so liable to deposit on standing or on subsequent dilution.

(2) The organic matter present in it is less putrescible than that present in a percolating filter effluent without subsequent straining, and consequently less call is made on the nitric nitrogen.

(3) The purification effected in strong sewages by double contact is considerably greater than by a percolating filter.

(4) It is also probable, admitting that pathogenic organisms are largely destroyed by the presence of overwhelming numbers of other organisms, that the prolonged contact in bacteria beds is more inimical to their development than the short period of contact on the percolating filter.

20807*. What test or tests do you chiefly rely upon in judging of the quality of an effluent, and for what reasons?—We rely upon the following tests :—

(1) The amount of probably putrescible matter as measured by the albuminoid ammonia and oxygen absorbed tests.

(2) The total purification as measured from the improvement effected on the albuminoid ammonia on the crude sewage, because the greater the purification effected the less liable is any remaining organic matter to subsequent putrefaction.

(3) The amount of nitrification which has been effected, and the condition of this nitrogen

(whether nitrous or nitric), because this figure shows not only the state of purity at which the sewage has arrived, but also what reserves it has to draw upon.

(4) The rapidity with which an effluent absorbs dissolved oxygen, either with or without dilution. This test shows whether the effluent is likely to be inimical to fish life or not by making any subsequent call upon the oxygen of the stream.

(5) The amount of suspended matter in the effluent and the proportion of organic to inorganic, as nuisance may be caused in the stream owing to the deposit of such material.

20808. Have you tried the "aeration" test, *i.e.*, the rate at which dissolved oxygen is taken up by an effluent?—Yes; we have supplied the Commission with a series of figures we obtained from this test (*See Appendix*, page 71).

20809. Is one standard for all effluents passing into non-potable streams possible and desirable?—No; we do not think it possible.

20810. Should there be more than one standard, and, if so, how should a plurality or series of standards be formulated?—We consider it would be advisable to have a plurality or series of standards which would take into consideration the strength and volume of the sewage and the velocity and volume of the stream at the time of discharge. The standards to be adopted might be arrived at by mutual arrangement between the rivers authority and the local authorities. In case of dispute the matter should be referred to the Local Government Board or some specially constituted authority for arbitration.

20811. What is your experience of the effect of storm water upon filters of various sorts?—We have not made any experiments in the use of storm water beds other than those mentioned in reply to question No. 20723.

20812. How far do you consider it advisable for a sewage installation to be worked automatically?—We do not approve of automatic installations in works of any size. In small works they may sometimes be necessary on economical grounds; but even then frequent supervision is necessary.

20813. Have you made any systematic observations as to the effects of discharging effluents into watercourses?—No. As regards possible damage to fish life from effluents, we may say that a number of small fish were kept in a tank fed by second contact bed effluent only, for a period of nine months. During this time they were quite healthy. They were finally washed away by an excessive flood.

20814. Could you make a short statement setting forth the values you attach to the different chemical tests in use for determining the qualities or conditions of sewages and effluents, and giving your reasons?—The four hours' oxygen test is a useful comparative test where sewages of the same character are being examined daily. The albuminoid ammonia is a still more useful figure for judging the amount of treatment that the sewage is likely to require or the amount of unfermented organic matter present in an effluent. A nitrogen determination by the Kjeldahl method is, however, much more satisfactory than this latter, because the ratio of albuminoid nitrogen to the total nitrogen obtained varies enormously with the strength and condition of the sewage. The three minutes' oxygen test is a useful indication of the amount of trade effluent in the sewage. For effluents the dissolved oxygen test is of the greatest possible value. The simpler the method the better. The rate at which oxygen is absorbed by the effluent during given periods of time is one of its most valuable applications. The nitrites and nitrates indicate the reserve which the sewage has to draw upon independently of the dissolved oxygen, and also to what extent the sewage has been purified.

20815. What are your views with regard to the quantitative determination of the "strength" of a sewage, tank liquor, etc.?—The most important points to be determined in a crude sewage are the suspended matter and the ratio of organic to inorganic matter in the same. This will give some idea as to the quantity of sludge which has to be dealt with. The saline and organic ammonia should be determined as an indication of the organic strength of the sewage. The three minutes' oxygen absorbed should be used as an indication of the amount of trade effluent. The determination of the amounts of grease and cellulose would also be most useful, and in some cases absolutely necessary.

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross. F.I.C., F.C.S.

9 May 1905.

TANK LIQUOR.

In the tank liquor an additional amount of ammonia should be found, and there should be a considerable diminution in the amount of suspended matter. An increase in the oxygen absorbed would indicate over septicism.

PRIMARY CONTACT BED EFFLUENT.

It depends to a large extent upon how it is to be subsequently treated. In working with double contact the first contact bed continues in a measure the action of the septic tank, but aerobically instead of anaerobically. We should look for a decrease in the free ammonia of 40 per cent to 50 per cent., and about the same on the albuminoid ammonia. Hydrolysis is requisite, but not nitrification.

SECONDARY CONTACT BED EFFLUENT.

The free albuminoid ammonia should be reduced as low as possible, indicating that little fermentable matter is present. The oxygen absorbed figure should also be low for the same reason. The nitric nitrogen should be high, as it indicates how far organic nitrogen has been converted into inorganic nitrogen.

20816. (*Chairman.*) On question 20713, do you know why the sewage was stronger in 1904 than it was in 1903?—(*Mr. Raymond Ross.*) Yes; there was a very much greater rainfall in 1903 than in 1904—very considerably; 1903 was a very wet year, 1904 was a very dry year, one of the best years we have had.

20817. (*Mr. Power.*) Are these averages of the months, then, for each year?—Yes, sir; we took samples every day; some days two lots of samples completely through, and at the end of the month they are all returned to the Highways and Sewage Committee with all the analyses—all the details of them—and they are all averaged up, and this is the average of the averages.

20818. You add together twelve monthly averages and divide by 12?—We add the whole twelve months together and divide by 12; about 2,700 analyses per year are included in this.

20819. Are included in this?—Are included each year; about 2,500 to 1,700 are included each year, and these are the average of these analyses.

20820. (*Chairman.*) Then question 20716, do you think that any one figure would give you a fairly approximate idea of the strength?—I think it might, as a rule, in any district where you knew the circumstances, but I think the figure might have to vary according to the district in which it was being taken; that is to say, you would have to take cognisance of the method of purification which was adopted and the original strength of the sewage.

20821. Question 20720, I see these figures are lower than your average of suspended solids in dry weather, and I suppose that is due to the fact that in the very early part of the storm the sewage, apart from the storm, would contain very few suspended solids, and that these given in the table are almost wholly due to the storm?—Yes, my Lord, that is it, and there were not quite so many. We have not had a large number of analyses. We did not get these questions in time to take a very large number, and they were taken under conditions that just existed at the time; but the other ones have been taken over a long period, and consequently they are hardly comparable between each other. It was a question in your questions that suggested doing what we could in the time that we had before sending in the answers.

20822. (*Mr. Power.*) The figures given by you in reply to Question 20720, those are storm sewage figures, not storm water proper, are they?—They are.

20823. The average sample during the first, second, third, and fourth hour; it is Question 20720?—These are tank effluents.

20824. They are tank effluents?—Tank effluents.

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

20725. Your minimum in Question 20711 was 83 parts?—No, I am wrong, sir; they are not tank effluents, they are crude sewages; these are crude sewages.

20726. Containing a very large proportion of storm water, I suppose?—Containing a very large proportion of storm water. We get ours very quickly, because it is very hilly, and all the streets are paved, so the storm water arrives very quickly at the works and in considerable volume, and only a short sewer. (*Mr. G. H. Pickles.*) It is about one and three-quarter miles from the centre of the town.

20827. (*Chairman.*) I am not quite certain of Question 20723. You do not appear to me to state quite definitely whether running the first part of the storm sewage through the tanks and filters is likely to cause damage or not?—(*Mr. Raymond Ross.*) No; I think not, my Lord; as long as it goes through the tanks I do not see that it can do any particular harm if your tank capacity is sufficient. The thing is not to throw your suspended solids up too highly in the effluent from the tanks—the tank effluent. You see every 12 parts of suspended matter means that for two million gallons it would work out to a cubic foot of material carried into a bed; so I think it is purely a matter of how big your tank capacity is so as to get rid of a sufficiency of suspended solids.

20828. (*Mr. Power.*) But do you, as a matter of fact, pass much storm sewage through your tanks? I see your dry weather flow is 2,500,000 to 2,000,000, and your maximum in 24 hours is 9,000,000. Do you take four times the dry weather flow through the tanks, as a matter of fact?—Three times the dry weather flow; then the big detritus tanks; at the side we have two very large detritus tanks, and those have long sills which overflow at three times the dry weather flow, so that by regulating the sluices which lead into the septic tanks we can send three times through the tanks continually, and let the rest overflow after passing through the big detritus tanks.

20829. After passing through the big detritus tanks then that goes to the ponds you speak of?—It joins with the other effluent. Unfortunately we have no separate channel, although in our scheme we have provided for another channel to take this water separately. That is not yet constructed, but it is intended to deal with the water separately to the overflow water. At present it is simply allowed to mix with the other. (*Mr. Pickles.*) Of course, all the sewage which arrives at the works must pass into one or other of the detritus tanks, but there is an overflow from those detritus tanks which intercepts the sewage—that is, the storm sewage—so that only three times the dry weather flow passes through the septic tanks proper. Then, of course, the overflow joins the main conduit again, mixes with the tank effluent, and then runs in the common conduit to the farm. Then, of course, part is dealt with on the contact beds, and the remainder on these land areas.

20830. Is the 9,000,000 gallons that comes down to you in 24 hours now the maximum that the sewers will carry?—Well, the conduit has been running within four inches of the top; it is practically the maximum that the sewers will carry. Of course, storm overflows would be working at that time.

20831. You are contemplating doing away with some storm overflows and raising others, so in time to come you will have more to deal with in storm than now, will you not?—We shall, sir.

20732. And so far as the sewers will carry it you deal with that on your present plan. You now deal with some of it in the ponds. Do you not let that extra amount go into the tanks? Will not your storage at the works have to be bigger the more storm water you get down in the 24 hours?—In any case, we would only take three times the dry weather flow through the septic tanks, and then the remainder, after passing trough the detritus tanks, would be carried by the separate storm water conduit to the farm, which is three-quarters of a mile lower down, and dealt with on the land.

20833. On the land?—So that the storm sewage would not mix with the tank effluents.

20834. Quite so?—It would be separate from the tank effluents.

20835. Three volumes would be dealt with, and other three, five, or additional volumes would be dealt with in this way?—Yes, sir.

20836. (*Chairman.*) Then, in your answer to Question 20735, you say when sewage, precipitated by lime and copperas, was treated on contact beds, you obtained fairly good results; but you think that better results were obtained by doing away with precipitants and using septic tank effluents. Well, now, do you speak positively on that point?—(*Mr. Ross.*) Yes; I think I may speak positively on that point in this way: that although I did not do all the analyses (I had not come there when a number of the analyses were done) still copies were lent to me of these analyses, and I know it was my predecessor's opinion, although he only had a very short experience; in fact, a month or so. He only tried it on quite a small scale, and the results we obtained afterwards were undoubtedly very much better, or considerably better; I will not say very much better. They were distinctly better right throughout.

20837. (*Mr. Power.*) But you have distinctly less suspended matter in the effluent from the chemical precipitation tanks?—There would be less suspended matter, but I think now that we have enlarged our tanks we have still reduced the amount of suspended matter sufficiently.

20838. Your septic tank effluent, what does that contain now?—Five to seven parts per 100,000 on the normal weather flow; I do not mean the dry weather flow, but a normal weather flow.

20839. The suspended matter in the raw sewage is very high indeed?—In the raw sewage it is very high indeed, but then we have, you see, rather over 24 hours, really.

20840. Rather over?—It is a little over 24 hours' dry weather flow, and we have taken a considerable number of estimations of suspended matter, and it will vary from five to seven, except during times of prolonged storm, when it goes gradually up, and the highest we have had is nine.

20841. From the septic tank?—From the septic tank. Of course you must still remember that we are not in the position of having a separate conduit yet; it has not been built, so that what arrives at the works at the present moment will contain more suspended matter because it has the overflow from the septic tanks mixed with it.

20842. You mean more than three volumes will go through the septic tanks then?—No, I do not mean that, sir; but the overflows from the detritus tanks mix with the septic tank effluents, because we have not built the new conduit.

20843. It comes to the filters?—It comes to the filters; we cannot help that at present till we get this fresh conduit. It is simply unfortunate that it is so, but it does not interfere with the fact that we can bring our tank effluent down to three to six parts, to an average of five to six parts of suspended matter, taking three times the dry weather flow. (*Mr. Pickles.*) I can support what Mr. Ross says with regard to the result of the chemical precipitation. Of course I took part with Mr. Harris, who was Mr. Ross's predecessor in these experiments, and although I have not the figures I remember that the albuminoid ammonia is distinctly less than it was before.

20844. (*Colonel Harding.*) Were the conditions the same; was there the same length of contact; were all the conditions the same?—Yes; there was not quite the length of septic tank contact, because there was only the old set of tanks working.

20845. Might not it be that the conditions of the first experiment were different from those of the last experiment?—There was about the same contact with the septic tanks.

20846. Was the material the same; were there the same filters, or were they analogous filters?—These filters were the same. (*Mr. Ross.*) I think I know which the filters were—the ones really that most of my ideas were based upon were No. 19, which is still working; it is absolutely the same bed, as it has never been touched.

20847. Anyway the experiments were not simultaneous; they were at some hours' interval?—Oh, not simultaneous. (*Mr. Pickles.*) Oh, no; of course the precipitation was in vogue; but then, of course, it was changed to the septic treatment.

20848. You are comparing the present results that you obtain from septic effluent filtration with the

results obtained some time ago by the filtration of precipitate?—Yes, that is so; we get a clearer tank effluent certainly with chemical precipitation.

20849. (*Mr. Power.*) The effluent from the precipitation tanks was at that time greatly in excess of the effluent from the septic tanks?—No, it was about the same, sir.

20850. (*Colonel Harding.*) Was the volume which you passed the same; was the sewage about the same strength—Yes, it was about the same strength as far as I remember.

20851. Your answer interests us because it differs from the opinion which has been formed elsewhere?—Of course I am simply basing my answer on the albuminoid ammonia figures; those were what we chiefly relied on at that time, and those are what we have submitted to the Committee.

20852. We take it that you have made no simultaneous experiments for the purpose of ascertaining the comparative results?—You may, sir.

20853. You have not made?—Yes. (*Mr. Ross.*) We did find one thing, sir, which is perhaps important, and that is that when using precipitants we got a considerable amount of iron deposited in our contact beds, particularly in the second contact beds; it did not seem to come down so much in the first as in the second contact beds.

20854. And do I gather that you found the septic action more useful in precipitating iron?—Oh no, this was adding copperas.

20855. Oh, I see?—This was adding copperas, and then iron came down and went towards filling the bed; that was all—not interfering with purification.

20856. You have no iron salts coming down in your sewage?—None at all, sir.

20857. (*Mr. Power.*) It was detrimental to the beds, you mean?—Detrimental as regards filling up the bed, as regards causing filling.

20858. (*Chairman.*) You got rid of all your sludge, what I may call your precipitation sludge, at 10d. a ton; can you get the same price for what may be called septic sludge?—Yes, my Lord, we get exactly the same. The lime is of principal value. Our country round has very little lime, and the farmers really like this because of the fibre in the lime mixed together; the amount of fibrous material in the lime; it suits their land and makes it lighter and better.

20859. Then with regard to Question 20744; you say, in reference to septic tanks, "scum is, we believe, desirable." Do you believe that very firmly?—I do believe it rather firmly, but I do not know that I can give any very definite reason for doing so.

20860. (*Colonel Harding.*) Perhaps you would indicate a reason why it is of value. You say, do you not, that you have not found any difference in the purity of final effluents when there is and when there is not a scum?—No, we have not.

20861. Seeing that there is no difference, why is it desirable to have one?—Well, I think in one sense it prevents the variations of temperature, which must really affect purification, although we may not be able to detect it. Sewage is always varying in strength, and you are taking more or less of an average, and it is very difficult to compare one week's flow with another week's flow unless you have very accurate gaugings, which unfortunately we have not.

20862. Am I right in thinking that you think scum is useful in conserving the heat of the sewage?—Yes, in conserving the heat of the sewage more than anything else, and so obtaining a more even temperature.

20863. (*Mr. Power.*) You do not think covering the tank is of any advantage, do you?—I do not think it is of sufficient advantage. It keeps the temperature a little more even, but nothing else; it does not get rid of any more sludge; there is no nuisance when it is not covered, and therefore it is a big expense for practically nothing.

20864. (*Colonel Harding.*) You have not tried whether there is any difference of temperature in the presence of scum and in its absence?—No; I have tried in a covered septic tank, an ordinary tank, and the temperature in the covered septic tank is invariably a few degrees higher. I have for 12 months the figures taken twice daily, and the average was some few degrees higher in the covered septic tank.

20865. (*Mr. Power.*) With and without scum have you tried it?—No, we started it as soon as a thin scum got formed; we did not take it till the thin scum had formed.

20866. (*Sir William Ramsay.*) Does your scum come and go; does it occasionally appear and disappear again?—Only at the very beginning. If it once forms anything like an inch thick it will never go again—it stays.

20867. (*Chairman.*) Well, at Question 20755 you found the suspended matter in the tank effluent rose to about 35 parts per 100,000 at the end of six months. Now, I suppose, you would consider 35 parts was an excessive amount to put on to a contact bed?—Yes, my Lord, very excessive. This is why we made our tank capacity so much bigger.

20868. Then Question 20769. I presume from your answer you do not find that the soil in any way tends to work out into the filters?—Not in the very least. We dug down for several people to see them, and I think everybody who has seen it has been convinced. (*Mr. Pickles.*) In fact, we have dug down to put in perforated pipes in many places instead of the ordinary field tiles, and we have not found the bottom to work up, neither have we found it in the washing and cleaning of a bed; we have taken the material out without any difficulty.

20869. (*Major-General Carey.*) Can a contact bed be considered absolutely water-tight?—(*Mr. Ross.*) Yes, sir, absolutely. We have tested that in this way with the pipes coming up at the end of the herring-bone, so that we can dip these pipes and take a dip on to a stick; take that at the end of two hours, and you will not see any difference that you can possibly detect—in fact, there has been no difference found.

20870. When the bed is empty during periods of rest is there no evidence of leaking when it is exposed to the sun?—It does not seem to; it never has done; we have never had any leaking. The only leaks we have ever had—the whole of the land was originally under-drained, and sometimes one of these, in making a new bed, had been missed out, and then when the new bed started a leak has been found, and it has always turned out to be one of these old under-drains; of course, we have had to go down till we found it, and stop it, and then there has been no further bother.

20871. (*Chairman.*) Then my last question is on 20807. In answering Question 20799 you mentioned that you have had no personal experience of percolating filters; well, then on 20807 you give us the differences between the effluents from a contact bed and the effluents from a percolating filter, and I only just wanted to know what you go upon?—Well, I thought I had stated the results were given to Dr. Fowler, of Manchester, when he was going to read a paper before the Sanitary Congress at Glasgow. He asked several works, and amongst others ours and Accrington. Well, I got, of course, naturally a copy of his paper; I was also there when it was read, and they gave their cost and their purification according as they are set down in this report; they gave their purification as 75 per cent. on the tank effluent at Accrington.

20872. Yes. Did you take the qualities of the effluent from the same standpoint?—From the same standpoint, because the two towns are very close together and very similar. I think it is fair; they are only about six or seven miles apart, and they are both Lancashire mill towns. One is perhaps twice the size of the other, but that is practically as far as I know the only difference. They are worked on very similar lines, and therefore I thought they were comparable.

20873. (*Colonel Harding.*) Is your answer based on any experience of your own?—No.

20874. You have not tried any comparative experiments?—No, sir.

20875. With your own sewage, with percolating and contact filtration?—No, we have not fall enough; we have often wished to do it; but we have not fall enough to do it.

20876. What you are telling us is what you have got through every filter?—What I am telling you is what we have got through every filter.

20877. But in your answer to 20806*, the third part of the answer, you refer to the deposit of sediment on standing, even on admixture with rain water, as being a peculiarity of percolating filtration. In what cases

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

have you found this?—Merely in the cases where iron salts are present; I think it often takes place. A man from Hamburg, Dr. Dunbar, in reading his paper at Glasgow, showed a number of effluents which he had brought over, and they were all percolating effluents, and they nearly all had sediment deposited in them.

20878. You have no experience of your own?—No, sir, but it led me to think that it might be important if that were the case as a rule with them.

20879. There are one or two questions I should like to ask you in regard to trade effluents. You have answered Questions Nos. 20709 and 20710, and I think we gather from those answers that you have had no serious trouble with trade effluents, provided they do not come to you in rushes, if the manufacturers send them down in a regular flow spread over the 24 hours you are quite ready to deal with them?—Yes, sir.

20880. And you tell us that where it is proposed to send a trade effluent into your sewers you make a special arrangement?—Yes, sir.

20881. Have you any general rule to guide you in making that special arrangement; your Corporation has not framed any rules?—(*Mr. Pickles.*) No, we have not; we simply rely on the general Act, and when plans are presented of dye works and extensions we generally get a note put on the plan, and we have no difficulty in getting the owners to carry it out.

20882. What do you ask them to do—settle solids?—Well, as a rule we ask them to put in a tank, a measuring tank, if there is no great quantity of solids present, and then they pay the Corporation so much for treating the sewage, so much per thousand gallons.

20883. You make a charge to them?—We make a charge to them.

20884. But you endeavour as far as possible to get them to send their trade effluent in a regular stream?—Yes, sir.

20885. And not to empty the tanks in rushes?—No. Of course the object is really to keep control of trade effluents.

20886. Have you formed an opinion as to the policy that you should follow; is it better that you should urge upon the manufacturers to treat their own, or do you think it is best that the Corporation should deal with trade effluents *en bloc* subject to certain conditions and charges?—Well, in our case the works are very small, and I do not think it would be advisable to insist upon separate works being put up.

20887. You think it is better for you to do it *en bloc*?—Yes, as far as we are concerned.

20888. Now, in regard to the suspended matter in your sewage, the average of which appears to be very high—119 parts per 100,000. In your answer to Question 20711, I find that. That is a very high average?—(*Mr. Ross.*) Yes.

20889. You have a great deal of suspended matter?—Yes, sir, we have.

20890. On the other hand I notice that in your septic tank effluent you have succeeded in getting a reduction down to 3 to 5 parts per 100,000?—Yes, sir.

20891. It seems exceedingly small, and a very successful result?—Yes.

20892. One is interested to know how you have obtained it. In most other cases we find that septic tank effluents carry away with them a much larger quantity of suspended matter—three or four times as much, and one is interested in knowing by what means you have accomplished this excellent result?—Well, I think one great thing that has helped us towards it is putting in very large detritus tanks. You see we have very large detritus tanks. That takes up such an amount, having each of them to be sludged every third week, so we get rid of a very great deal more of the heavier matter there than in the other tanks; we have very long sills now; the sills extend the whole length of the tank—the outlet sills. I think that makes a great deal of difference, because it prevents not only the formation of currents, but any depth of water over the sill.

20893. It flows over a very thin film?—It flows over a very thin film indeed.

20894. And there is a very small current?—Practically no current.

20895. On the other hand, is there not a discharge in drawing in that way from the top—from the surface of the septic tank?—Oh no, the sill is two feet down below the water level.

20896. The sill is a secondary sill?—Yes, sir.

20897. The sill is not in the tank itself?—(*Mr. Pickles.*) We have really a scum bar, and the bottom of the scum bar is 2 feet below the water level, so that really the sewage has to rise up under the scum bar.

20898. You do not carry away what is floating on the surface?—(*Mr. Ross.*) Oh no, sir.

20899. Then what is the total capacity of your tanks, detritus, septic, and other, in relation to the flow; does it represent one day's flow?—I think 28 hours; without the detritus tanks it is about 28 hours.

20900. And with the detritus tanks?—It would be somewhere about 30 or 31; I could not say exactly.

20901. Then you attribute the fact of your having so little of the suspended matter in your septic tank effluent mainly to the fact that you have large detritus tanks which are frequently emptied and are not allowed to become septic?—Yes, sir.

20902. And that you take the sewage from the septic tanks themselves in a very thin film?—Yes, sir.

20902*. (*Mr. Power.*) Your septic tanks, do you sludge them frequently, as well as the detritus tanks?—The septic tanks will now only be sludged once a year.

20903. Once a year?—I think they will be only; of course we cannot quite say, because we have not run long enough with these new tanks.

20904. And your septic tanks that you have been using formerly you have been sludging every six months, because they have been smaller?—(*Mr. Pickles.*) We have been sludging every six months, but we hope to be able to run 12 months without sludging, but still at present we cannot say definitely whether we shall be able to do so; we may possibly have to sludge every six months still.

20905. And when you sludge the septic tanks you clear them completely, do you?—Completely.

20906. (*Colonel Harding.*) The question Mr. Power puts to you raises a very interesting point. You say you sludge, and you are proposing to sludge at longer intervals; you say you have been sludging at six months, and you hope to reach an interval of 12. When you do sludge you hope to bring everything away altogether. Am I right?—(*Mr. Ross.*) Yes, sir.

20907. Do you not find a new septic tank takes some time to mature and reach full septic conditions?—We have side sluices.

20908. And therefore, after fully emptying a septic tank, you pour into it some septic sludge for the purpose of inoculating it?—Septic liquor rather than septic sludge.

20909. Septic liquor?—As little sludge as possible.

20910. Do you find in that way that on re-starting septic conditions are rapidly reached?—Yes, sir.

20911. Is there any inconvenience in emptying a septic tank at long intervals, say after six months or 12 months, in this respect—that you are having a constantly varying capacity? If you find a certain capacity to be necessary, that capacity of course is being reduced, so that at the end of six months or 12 months it may be the capacity is only half, and therefore the flow is double. Would it not be better—I mean theoretically—instead of emptying at long intervals, to empty very frequently some portion of the sludge out of the septic tank, daily or weekly if it were possible?—In one sense it rather balances itself. Supposing we empty say once a year, and we have 17 tanks; these tanks would be sludged in such rotation that the process of emptying would occur at intervals, so that the capacity of the tanks is very much the same throughout. As we are sludging No. 1, No. 17 has just been sludged; then we turn to No. 1, so that the tanks are always somewhere about the same capacity. Of course, one is at its maximum age and one is practically new, so we are always going round them.

20912. Still in regard to the individual tank, the fact remains that in that case the flow is much greater when the tank is full of sludge?—Yes, sir.

20913. And it might at least be theoretically desirable to maintain a constant capacity by emptying some sludge out frequently?—I think it would be desirable

that we should, if we could, get the sludge pumped without emptying at all; I think it would be the very greatest blessing; the only difficulty is that it so interferes with the work of your presses. You cannot always get sufficient for pressing, and the things do not run as regularly and as economically from a pressing point of view necessarily; they may or may not.

20914. How many tanks have you altogether?—Seventeen, sir.

20915. Instead of your presses depending upon the emptying of one of the 17, it would come to the same thing if 1-17th of each was taken off more frequently, would it not?—It would mean a lot of opening of valves.

20916. But you agree that it would be desirable if it were found practicable?—If it were found practicable, and practical too.

20917. And maintain a constant capacity in the septic tanks?—And, if you could, mix the lime with the sludge.

20918. You have not estimated the digestion?—We have not had gaugings sufficiently accurate to be able to do so.

20919. At least you have formed the opinion that there is not a complete digestion of the suspended matter in the septic tanks?—Oh, no. (*Mr. Pickles.*) I may say with regard to the periodical sludging of the tanks that we did attempt at one time to sludge frequently—that is, without emptying the tank by drawing off the sludge by a sluice at the bottom of the tank; but we found that there was so little sludge came away, and that we got so much sewage with it, that it was not practicable in our case.

20920. The amount of lime that you add to the sludge appears to be very considerable?—(*Mr. Ross.*) Yes, it is; it will not press without it, unfortunately.

20921. Adding that very large quantity of lime to the sludge, you have no trouble at all?—No, sir, no trouble at all; we get very good cake, very solid and firm. (*Mr. Pickles.*) We attribute the success partly to the thorough admixture of the lime with the sludge.

20922. (*Sir William Ramsay.*) I was going to ask you how is the mixture made?—In sludging the tank the sludge is pumped from the tank into the detritus tank, and lime is added at the inlet.

20923. So that it mixes very thoroughly on its way in?—It mixes very thoroughly on its way in; it is really twice mixed. I think we explain that fully in our evidence.

20924. (*Colonel Harding.*) Let me pass on to the question of the contact beds. You tell us that you think the size of the contact beds should be as large as may be conveniently filled in two hours?—Yes, sir; one and a half to two hours.

20925. Would it be an advantage to do it in a shorter period?—One and a half to two hours we have found most convenient, so that we can have the whole flow of sewage on one bed.

20926. But if you had a unit which you could fill in one hour would you not have the advantage of a longer period of rest?—You see the sewage varies, and we keep our larger beds for the larger flow.

20927. Still, the fact remains; would there not be an advantage in having your beds of such size that you may fill them in a shorter time than two hours?—(*Mr. Ross.*) I think it would be good that way if we were able to work more than twice a day; if we were able to fill our beds more than twice a day it would be an advantage, but I think if we fill our beds oftener than twice a day we do not get a good effluent; it seems it will not go.

20928. Because you do not get then sufficient periods of rest?—Yes. There would be an advantage. You see the beds have plenty of rest the way we work them.

20929. Filling only twice a day, what is the length of the cycle 12 hours?—Of course, it is always varying with the weather; in dry weather, such weather as we are having now, it would take 15 hours to fill the beds once.

20930. You mean 15 hours for a cycle?—Fifteen hours for a single cycle, just to fill our contact bed once.

20931. Then there are times when it takes you much longer than two hours to fill a bed?—Yes, there are times when it takes us much longer, but then we should use the small beds in dry weather like this.

20932. It occurs to one if you could fill your beds much more rapidly, in one hour say, it might give you that hour for valuable rest?—I do not think we should materially gain, because filling only twice we have a sufficient period of rest.

Mr. H. C. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

20933. What period of rest do you have?—Well——

20934. Six hours?—Yes, six to eight hours altogether.

20935. And that you think is sufficient?—I think it is sufficient, yes.

20936. So that with two fillings a day you think the unit should be such as may be filled in two hours?—It has worked very well and very conveniently.

20937. Now on the question of the reduction of capacity of contact beds you have given us certain very interesting figures, but what interests me particularly is that you have given us from actual experience of your own the cost of washing the material of the bed?—Yes.

20938. How long now do you think it would be possible to run your contact beds before you reach the necessity of washing out the material; how many years?—(*Mr. Pickles.*) With what has been washed, sir?

20939. No. Suppose you put down a new contact bed; how long do you expect you would be able to run it before you reached the necessity of washing the material?—If the bed is screened and washed in the first instance, as we advise, we think that it would last certainly for seven years.

20940. For seven years?—Yes, if not longer.

20941. (*Mr. Power.*) A primary bed are you speaking of now?—A primary bed, yes, sir.

20942. (*Colonel Harding.*) The secondary bed I suppose will last much longer?—(*Mr. Ross.*) Probably twenty, I think. (*Mr. Pickles.*) We do not propose to wash the secondary beds.

20943. Then you think that will not be necessary?—We think not.

20944. Now down to what point do you propose to reduce the capacity before you wash it?—(*Mr. Ross.*) About 30.

20945. Do you mean 30 per cent.?—No, I mean about 30 gallons per cubic yard.

20946. Well, then, turning to the table that you have given us in connection with your reply to our Question 20783 you there speak to us of contact bed No. 5, and you say that the capacity originally, in June, 1904, was 79 gallons per cubic yard?—Yes, sir.

20947. And that that was reduced down to about 30, I suppose?—49·22, on February 23rd.

20948. Within what time; June, 1904, it was 79; when does it reach 30?—It has not reached 30 at all yet. (*Mr. Pickles.*) The last gauging on February 23rd was 49·22.

20949. Then after nine months it has fallen from 79 to 49?—(*Mr. Ross.*) Yes, sir.

20950. Nevertheless you think before it reaches 30 it will be seven years?—I do, because we have one now that was not screened or washed, that has been working over seven years—seven years last February; that still stands at 24.

20951. That is an instructive and interesting experiment, and we gather from you that under your conditions you may work your primary contact beds for seven years before you reach the necessity of washing, and that when you do wash, from the experience you have actually had it will cost you a shilling per cubic yard?—That is so.

20952. That would point, would it not, to the fact that in many cases it would not be necessary to so completely clarify sewage as to reduce the suspended matter to an absolute minimum?—Oh, quite, yes.

20953. That you can deal upon contact beds with, in your case, you think, 5 grains?—Five parts per 100,000.

20954. Five parts per 100,000 for seven years before needing to wash?—Yes, sir.

20955. That is a very small quantity?—Well, we have had far more than that going in during these experiments, because these new tanks have only just been completed; these new tanks have only been working a few months, so all these are worked with the old tanks.

20956. What quantity of suspended matter?—The suspended matter would be about 15 in this case.

Mr. G. H. Pickles, A.M.I.C.E., and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

20957. Fifteen?—Twelve to 15.

20958. Would it not be about the average through the life?—Twelve to 15 throughout all these gaugings.

20959. Are we to take that in your experience—putting 15 parts per 100,000 on to a filter it will last for seven years?—It will last for seven years.

20960. And then it can be washed out at a shilling per cubic yard?—Yes, sir, but the cost is not included in that shilling; the cost of the material which would replace that which is screened out. (*Mr. Ross.*) Well, the cost of carting; the cost of washing and screening the extra material required is included, but the cost of collecting and carting the material down to the works is not included. You see you have a certain amount of waste, when you clean a bed, that has to be replaced.

20961. But you include the primary?—We include the primary, but not the carting.

20962. That would not very materially modify the figure?—(*Mr. Pickles.*) Oh, no, sir. In this table the bed worked continuously, and that is filled twice a day for six months without any periods of rest; we did not allow it any period of rest during that time because we wanted to see really what reduction took place.

20963. (*Mr. Power.*) Have you a fine layer on the surface which you remove from time to time?—(*Mr. Ross.*) No, sir; we have troughs, wooden troughs, and we can sluice those off at the back on to a small land area.

20964. You have not in this respect adopted the Manchester plan?—No, sir.

20965 Was this particular filter never filled more than twice a day, or did it take a chance with the others?—Twice every day whatever happened—it was always filled twice every day during the whole time.

20966. But not oftener?—Not oftener, and never less. (*Mr. Pickles.*) We have a photograph which may be of interest (*handing in photograph*). That just shows the surface of the bed.

20967. (*Colonel Harding.*) What is the age of the eldest bed?—Seven years last February.

20968. At times of storm, when the flow through your septic tank rises to three times the normal, do you not get necessarily a much larger quantity of suspended matter going on to the filters?—(*Mr. Ross.*) Oh, yes, sir; yes, we do.

20969. It is rather curious that in your earlier answers it would seem that in storm times there is very little increase, if any increase, in the suspended matter?—It went up to 9 on the occasion of a four hours' storm.

20970. In your answer to Question 20757?—It went up to 9 as far as I remember, did it not?

20971. In your answer to Question 20757 you tell us that at such times suspended solids averaged from 4 to 9·6 parts per 100,000?—Yes, to 9·6 parts per 100,000. That was taken during a storm; we could not take any number of these for your Commission, because we had not time after getting the questions; but we took the first opportunity of a storm to take a sample, and simply gave these figures; I am afraid they are not the average which I should have liked them to have been if we had had time.

20972. Accounting for the reduction of capacity in contact beds, you give, and very rightly give, great importance to the question of disintegration and consolidation of the material itself?—Yes.

20973. You do not think that the loss of capacity of contact beds is by any means due entirely to the indigestible or undigested matter coming down with the sewage?—Yes, sir.

20974. That is an important factor?—It is an important factor, but not so important as the other; the material is very important.

20975. The consolidation of the material must be due very largely to the fact of material being of uneven size, so that the smaller pieces work in between the larger and so tend to form a solid mass?—In a well-constructed bed I do not think there is so much consolidation as one would expect.

20976. But you say in your answer that consolidation and disintegration account almost entirely for the reduction?—Accounting almost entirely for the reduction: none of our material has been perfect till quite lately. I do not think it is perfect now; it has not been as good as it should have been. We have had a lot of destructor refuse, which was by no means properly burned, and other clinker. Well, you could rather call it ashes than clinker; and I think if you have real clinker, properly screened and washed, that the consolidation will be to a very great extent minimised.

20977. Then the consolidation naturally would be less with material of a fine size to begin with which would not disintegrate?—Yes, sir.

20978. So what you have to aim at is to get material of fine size, and such material as is likely not to disintegrate?—Yes.

20979. You appreciate the great value of that?—Very great. (*Mr. Pickles.*) Yes, sir. That is one reason why we have adopted the washing for new beds.

20980. (*Major-General Carey.*) I want to ask a few questions on Question 20723. Is any difficulty experienced in filtering three times the dry weather flow on the contact beds with septic tank treatment?—(*Mr. Ross.*) No, sir, we can do it easily.

20981. Is that owing to your efficient precipitation in the tanks?—I think we should do it anyway fairly efficiently. When we had a much smaller flow and more suspended matter we still got equally good results, but, of course, we were inclined to fill our beds to a greater extent; I think that is simply about the state of it.

20982. Are the present provisional requirements of the Local Government Boad complied with as to treatment of the storm water over three times the dry weather flow, either in special storm beds or on land, or on both combined?—We treat everything that arrives at the works now; we can treat everything one way or the other.

20983. You are aware of the provisional requirements of the Local Government Board?—Oh, yes; we can do that; we can treat three times the dry weather flow on contact beds.

20984. And over three times?—And over three times we can turn on to big land areas, and we do not run it through the roughing filters as they say, but we store it on these land areas and then run it on to storm beds, where we hold it in contact because we cannot get satisfactory results by running it through a roughing filter at all. We can keep practically all our effluent under the Ribble Joint Committee's standard by treating it in that way.

20985. Then the result of your treatment in this way has been so satisfactory as not to require any modification of the provisional requirements of the Local Government Board?—Well, I see your point. I think it depends very much how you look at it. I do not see why we should not treat three times the dry weather flow, but I do not see why we should take six times the dry weather flow down to the works at all.

20986. That is another point?—Well, that is part of the requirements. That is really where we should differ from them. It hardly comes in there, but it does make the difference why should more than six times in fact come at all any more than six times the whole, the sewage becomes so dilute.

20987. That we will come to presently, but at all events the answer to my question is that with the exception of the number of dilutions, assuming you have to treat so many dilutions, no modification of the requirements is required?—Except as regards method of treatment, which I think would be unsatisfactory. That is, if you are going to pass it through a roughing filter, I do not think you would get a satisfactory effluent.

20988. I think the requirements do not restrict you if put it on land as you are doing here?—We are only holding it up on land; we are not filtering it through land.

20989. Or land in combination with second contacts?—Or land in combination with second contacts; in storage; the land simply comes in as a storage tank; it is not really land treatment.

20990. Then Question 20728, in order to determine the number of dilutions at which storm and sewage may be passed into a stream, do you consider that the same mode of procedure should be adopted as in your reply to Question 20810 as to standards. There you say the standards to be adopted might be arrived at by mutual arrangement between the river authorities and the local authorities; in case of dispute the matter should be referred to the Local Government Board or some speci-

ally constituted authority for arbitration. Would you suggest that the same mode of procedure should be adopted in fixing the number of dilutions. If not, who is to determine the number of dilutions?—I think you would determine from the strength and general conditions of the sewage of the borough how much albuminoid ammonia, dissolved oxygen, and so on, should be present in the final effluent; that would be your fixing the standard; you would fix chemical standards.

20991. I am not on standards now; I am on dilutions; Question 20728?—After how many dilutions you should be allowed to run it into the stream?

20992. Who is to determine the point?—I suppose the rivers authority would be the first people to determine what they consider suitable for the state of their river, and if the chemist in charge advised his corporation, or surveyor in charge advised the Corporation, that the demand was unreasonable, then the matter would be sent for reference.

20993. Practically the same mode of procedure?—Practically the same mode of procedure.

20994. It would be by mutual arrangement?—By mutual arrangement as far as possible.

20995. Between the local authority and the rivers authority?—Yes, as far as possible and when possible. I might say in that respect that I do not think our river authority would raise any objection to it. Under certain circumstances, from what I have heard from Mr. Halliwell, I think he would be rather glad, provided all the first water were taken. That is what I think he objects to mostly, the first runs. Then, provided that were dealt with, that after the storm had continued for some time, and the stream had had time to rise to a definite height, that the remainder should go in.

20996. It could not be left optional with the local authority?—Oh, no.

20997. It would have to be sanctioned by a higher authority; by the Local Government Board, or some other authority?—I do not think we are sufficiently accurate for that, sir.

20998. (*Mr. Power.*) Do you not say that here in your particular circumstances, you think you get the washings of the streets and the yards delivered at the works before you ever get six times the dry weather flow there?—Yes, I think we do.

20999. And as matter of fact you have never dealt with six times the dry weather flow?—No, we cannot get the whole six times; before we get our drains full really it comes to our works. In our case before our drains are full it means such a short flow down to the works, and the town being both paved and hilly the streets are washed in a very short time indeed, and consequently it must arrive at the works before the drains become surcharged.

21000. You get a flood, as it were, at your works before there is any obvious flood in the stream into which your works discharge?—Long before.

21001. (*Major-General Carey.*) Now, Question 20733. On a separate or partially separate system, does not a considerable volume of foul surface water from roads pass untreated into your stream?—(*Mr. Pickles.*) Yes, undoubtedly.

21002. Which is objectionable?—Which is objectionable.

21003. And you have no means of treating it?—No, there are no means of treating it. Of course, we have not found any nuisance to arise from it, but certainly one must admit it is objectionable.

21004. No complaint has been made?—No complaint has been made either from the Rivers Board or from anybody else.

21005. It may be very polluting, of course, the first washings of a road?—I admit that, sir, yes.

21006. Then do you suggest that a separate or partially separate system should be carried out in an existing sewerage system?—Well, we have carried a partially separate system out in an existing system.

21007. In Burnley?—In Burnley, because, owing to the hilly nature of the town and the streets being paved, of course we get a lot of rainfall; the surface water is discharged into the sewers so quickly that the sewers become surcharged, and that causes flooding in the lower part of the town—in fact, not only in the lower part of the town, but in many parts of the town. The Local Government Board sanctioned a scheme for partial surface drainage. That has been mostly carried out, and it has completely cured those parts. At the same time I should not like to advocate the taking out of all the surface water, because we find that it is necessary to turn part of the surface water into the sewers in order to flush them. But from observations that I have made, and from the experience I have had in dealing with this, I think that there would probably be just as much harm done in our case—in fact more harm—in making sewers large enough to take all the surface water than in having them too small, because if you get them too large of course you do not get the self-cleansing velocity.

21008. Now, Question 20753: "How do you think the sludge should be taken out of the tank, and how should it be disposed of?" Does any nuisance attend the operation of removing the sludge from the septic tank?—Not at all, sir.

21009. You have never found that any nuisance has been caused?—We have never found that any nuisance has been caused.

21010. Is the supernatant liquid sent back for treatment or discharged into the stream?—(*Mr. Ross.*) It is pumped back. (*Mr. Pickles.*) From the tank it is pumped back into the inlet channel, and it goes through the tanks again.

21011. That is what I want to know?—After the sewage once arrives at the works we cannot discharge it into the stream until it has gone down to the farm, and either passed through the contact beds or through what we call the storm bed, which is also a second contact bed.

21012. In your reply to Question 20768 you say there is a saving of 60 per cent. effected by contact septic tank treatment as compared with chemical?—That is our experience.

21013. Now, Question 20779: Is 27 to 30 per cent. of the original water capacity of a bed a fair reduction in order to estimate the net average working capacity? You say you take 45 gallons per cubic yard per filling. That works out at 27 per cent. of the original water capacity; for the average working capacity; that is to say, for the reduction caused by the filtering material being put into the bed, and then for loss of capacity afterwards?—Yes, sir.

21014. And that 27 per cent. of course may vary a little, I think from 27 to 32 in other cases; but 27 per cent. in your case is a fair average reduction to establish working capacity?—Yes, we think so. Of course, we know that in many of our beds which we are now washing there has been a much greater reduction. Still, these beds have not been washed or screened, and we think we shall be able to maintain this.

21015. In your reply to Colonel Harding you said that the life of the bed can be maintained by washing the material at certain intervals; is that so?—(*Mr. Ross.*) Yes, sir; and I think, further, that the material that would disintegrate in the bed has actually disintegrated, and that therefore its second life ought to be longer still. That is, the oftener you screen a bed the better the residual material would be.

21016. Would you expect after screening and washing the material to recover the whole of the original capacity?—No, sir, no; what will disintegrate disintegrates, but there will come a point presumably at which the disintegration will be a minimum, where it will reach a minimum, and I fancy when that minimum is reached that the life of the bed will consequently have arrived at its maximum, which is considerably greater than it is under the present circumstances.

21017. Have you estimated the cost of renewing the filtering material for beds per cubic yard?—Entirely throughout, you mean; entirely new material?

21018. Entirely new material?—(*Mr. Pickles.*) Renewing?

21019. Renewing?—It would probably come to about 4s. per cubic yard.

21020. (*Mr. Power.*) For renewing?—This is including the cost of washing; that is the cost of the ashes, collection of ashes and washing and screening, about 4s. per cubic yard.

21021. (*Colonel Harding.*) But we gather from your answer to General Carey that you think it would be far better to wash the old material than to use new?—(*Mr. Ross.*) Much better. (*Mr. Pickles.*) I understand the question is what is the cost.

Mr. G. H. Pickles, and Mr. Raymond Ross, F.I.C., F.C.S.

9 May 1905.

21022. (*Major-General Carey.*) Of renewing?—Of renewing, yes.

21023. If you have to renew the material; if you do not find washing the old material produces the effects you anticipate?—Well, we think the washed material would be far better than the new material.

21024. Have you got any actual experience?—(*Mr. Ross.*) We have got over 12 months of a washed bed.

21025. Of washing?—Yes. We have got over 12 months of a washed bed.

21026. After the bed has been at work?—This bed has now been at work since June 15th; nearly 12 months, you see, it has.

21027. Using washed material?—No, that material has been washed. The bed has been working for some years, but on June 15th it was restarted as a washed bed, and since then it has been working constantly, and has given very satisfactory results, so that we have nearly a year's experience with a bed constructed of washed material—washed and rescreened material.

21028. Do you think you are justified in accepting that the life of a bed can be maintained by screening and removing the material and washing it and putting it back?—And filling in from new material what has been taken out and rejected, yes, sir, I think so.

21029. (*Sir William Ramsay.*) I have only one or two questions to ask. What is a tank?—(*Mr. Pickles.*) A tank is really a cess-pool. At one time in Burnley they were on the tank system, and instead of having the ordinary pail closet, as in most places, there was a wall-tank, or in some places an earthenware tank let into the ground, which was practically a septic tank. It had an overflow connected with the sewer, and this was allowed to be used until it got full, and then, of course, it had to be scooped out, which was a very filthy process. I am very pleased to say there are very few of those left now of either the pail or tank.

21030. Referring to Question 20716, have you made any experiments, Mr. Ross, in the way of getting at the strength of sewage by the quantity of oxygen required to oxidise it? You state here that you prefer a full analysis?—(*Mr. Ross.*) Yes.

21031. But have you made any experiments with reference to the quantity of oxygen required to oxidise it?—We have simply done the three minutes permanganate and four hours permanganate; we do these regularly.

21032. And not shaking up with oxygen?—I have done a considerable number of dissolved oxygen, a very large number, of which the figures, I think, have been supplied to you. I think there were about 270 or 280, and they were taken specially for it, filled into big Winchester quarts, so as to have a large quantity stoppered carefully down, and done as soon as possible both before and after incubation, as suggested by Dr. McGowan, at various periods.

21033. Would you not think that was really sufficient to give you a general idea of the nature of the sewage when you are working with very much the same substance?—I think it would if you are going to fix your standard knowing all about your sewage to begin with, and not going to make it a definite standard for everybody's sewage; I think so.

21034. For your own works it would suit?—For our own works I think it would do; but then you want to know all the circumstances in connection with the works before you could fix the standard which was required.

21035. Naturally, yes, I quite agree. What sort of chemical poisons did you test for?—Well, we know all the trade effluents that go into the works.

21036. There are none?—No, there are none, unless you choose to include gas liquor; of course, that is nothing.

21037. Referring to Question 20723, in which you speak of these land areas, I suppose it is not necessary to puddle those or to make them artificially; the clay is sufficiently non-percolating?—They are underdrained, but it does not matter if they do go through; it would only be land filtration in that case. But so little goes through that it is not worth troubling about.

21038. What is a leap weir?—That is used in connection with a storm overflow. It is really when the quantity of sewage arriving at a manhole attains a certain velocity, it leaps over the channel into the storm overflow, whereas if there is a small flow it has not attained that velocity, and drops down into an intermediate channel which carries it away to the sewer.

21039. Another question on Question 20729. Does the delivery of the surface water into the canal not foul the canal very greatly?—Well, we have had no complaints. There is a lot of suspended matter goes into the canal.

21040. But nothing that makes it smell?—No. (*Mr. Ross.*) I think the canal people are glad to get the water in our part. (*Mr. Pickles.*) And in the canal the water is constantly moving.

21041. The canal in no sense acts as a septic tank?—Oh, no, sir. There are so many locks on the section that the water is admitted at the high portion, and the water in the channel is gradually moving until it gets its outlet at the other end.

21042. Then at the end of Question 20733, I should like to ask is the river sludging at all in its lower reaches; is there any sign of sludging?—Oh, no. Of course, the river throughout the town is paved in the bed. You see they have a very small flow, and rather a quick velocity, and the sides of the river bed—in fact, both rivers—are pitched, sloped to the centre, and then an invert formed. Well, in ordinary weather, the invert, which is about 4 feet 6 inches wide, is quite sufficient to contain all the water coming down.

21043. And that gets scoured out by the water?—That is scoured out.

21044. It has got a smooth bottom practically?—Well, practically; the flow varies so much that instead of allowing it to run in a thin film over the whole width of the stream, about 30 feet wide, in which case there would be no scouring, it is thrown to the centre, and carried by an invert. That is really to prevent a nuisance. (*Mr. Ross.*) It is very hot sometimes, that is one thing. (*Mr. Pickles.*) It is used for condensing water. (*Mr. Ross.*) It is used for condensing water, and gets very hot.

21045. You state, in answer to Question 20794, to use contact beds as streaming filters would be very detrimental to the subsequent working of the bed; is that an answer given from some experience?—To a certain extent it is, sir. We have never been able to obtain any satisfactory results from streaming filters really at all.

21046. May I put it in this way: does it spoil the contact bed, or is it insufficient as a streaming filter?—Well, I was going to answer it in this way: we tried two contact beds, first and second contact, and then we tried constant streaming for a considerable period. We got very poor results indeed. I think we tried it for nine months, with two half-acre beds, and then we converted them back again, and it took a very long time before either of the beds got into anything like condition, two or three times the time that is usually taken to get a bed into condition.

21047. You have answered both parts of my question, both as to the beds and as to the sufficiency of the filter?—Yes, sir.

21048. In answer to Question 20807 you say that a contact bed effluent is superior to an effluent from a percolating filter. It is the second reason I wanted to ask you about. "The organic matter present in it is less putrescible than that present in a percolating filter effluent without subsequent straining, and consequently call is made on the nitric nitrogen." And also you go on to say, "The purification effected in strong sewages by double contact is considerably greater than by a percolating filter." Well, we have heard the answer to No. 3, but about No. 2. How did you manage to make the comparison as regards the putrescibility of the organic matter?—I have not had a great number of these effluents myself, but I have had a certain number, mostly sent at my request by friends, and some few sent in in other ways, and I have always found that with a percolating filter the dissolved oxygen is taken up very much more rapidly than it is with a contact bed effluent to a given point. After that point it does not go on as rapidly, but there seems to be an avidity for oxygen in the first rather short period.

21049. That is precisely what I wanted to find out—how you applied the test?—That is the way; I have tried it by hourly sample in that way, taking it each hour; and I have always found the few experiments, they are not a great number, but the few I have tried

have undoubtedly pointed to the fact that there is an avidity in a percolating filter effluent which is not noticeable in the second contact.

21050. Does it refer really to the liquid portion only?—That I cannot say.

21051. Have you tried it both ways?—No.

21052. It applies to the mixture containing solids?—I have simply taken the effluents as I have received them, without filtration in both cases; I have not filtered them.

21053. Then in reply to Question 20814 you make the statement: "The albuminoid ammonia is still a more useful figure for judging the amount of treatment that the sewage is likely to require, or the amount of unfermented organic matter present in an effluent." Might I ask you how you come to that conclusion?—Well, it seems to me that where you have a concentrated sewage in the ordinary sense—that is to say, a concentrated house sewage—you will have a very high albuminoid ammonia undoubtedly, will you not? Of course, where you have trade effluents they will be shown by the oxygen absorption in three minutes, so that you have got a guide in those two figures as to the amount of house or domestic sewage as against the amount of trade effluents which are probably present in the sewage which you are examining.

21054. But surely you are speaking merely of trade effluents which absorb oxygen readily?—Of course, one cannot say that it is any trade effluent.

21055. Any trade effluent?—Any trade effluent.

21056. In your particular case the trade effluents absorb oxygen readily?—In our particular place there are practically none that do absorb oxygen readily, but, for instance, in Manchester it is the opposite way round. No, that is just where the difference in the sewages would be found out by the difference in the analyses. In our case it is practically a domestic sewage.

BURNLEY.

Appendix to Evidence of Mr. G. H. Pickles *and* Mr. Raymond Ross.

Tables showing average analyses of sewage, septic tank liquor, and filter effluents at Burnley, January, 1903—December, 1904.

RAYMOND ROSS, F.I.C., F.C.S.

SEVENTY-THIRD DAY.

Wednesday, 10th May, 1905.

PRESENT.

The Right Honourable the Earl of Iddesleigh (*Chairman*), *presiding*.
Sir William Ramsay, K.C.B., F.R.S.
Major-General Constantine Phipps Carey, C.B., R.E.
Mr. W. H. Power, C.B., F.R.S.
Colonel T. W. Harding, J.P.
Mr. T. J. Stafford, F.R.C.S.I.
Mr. F. J. Willis (*Secretary*).

ALSO PRESENT.

Dr. A. C. Houston, M.D.
Dr. George McGowan.
Mr. G. B. Kershaw.
Mr. C. C. Frye.

Mr. Joshua Bolton, Manager of the Heywood Borough Sewage Purification Works, called in; and Examined.

Mr. Joshua Bolton.
10 May 1905.

21057. (*Chairman.*) You are Mr. Joshua Bolton, Manager of the Sewage Purification Works belonging to the Corporation of Heywood, and you have come before us to-day to give the results of your experience of sewage disposal works?—Yes.

21058. What is your general system of treatment of sewage at Heywood?—Chemical precipitation and subsequent single contact.

21059. What is the population draining to the Heywood works?—23,500.

21060. What is the system of drainage—that is to say, is the storm water either wholly or partially drained into a separate system, and if only partially, to what extent?—Combined; all storm water enters the sewers.

21061. Is there any infiltration of subsoil water into the sewers?—Yes. About 109,000 gallons per 24 hours in dry weather.

21062. What is the water supply per head, and from what source does it come?—The water supply is 20 gallons per head, and is collected on local hills.

21063. Is it hard or soft water?—It is soft water; total hardness 5°, permanent 4·6°, temporary 0·4°.

21064. What is the drainage area of the part of the town which is sewered?—525 acres.

21065. What proportion of the population use pail closets or middens, and what proportion use water-closets?—Pails, 3,783; middens, 6,039; total; 9,822 Fresh water closets, 1,211; slop water, 12,467; total, 13,678.

21066. Has the flow of sewage to your works been gauged? If so, what is the average number of gallons delivered at the works per day of 24 hours in dry weather, in winter and in summer?—Yes. The average of the winter of 1903 dry days was 774,510 gallons per 24 hours. The average of the summer of 1903 dry days was 629,172 gallons per 24 hours, a difference of 145,338 gallons per 24 hours.

21067. What is the maximum dry weather rate of flow, and at what hour does this occur?—The maximum dry weather flow is about 1,098,000 gallons per 24 hours, and takes place between the hours of 10 a.m. and 5 p.m.

21068. What is the minimum dry weather rate of flow, and at what hour does it occur?—The minimum dry weather flow is 324,000 gallons per 24 hours, and takes place between 1 a.m. and 6 a.m.

21069. What is the maximum wet weather rate of flow which you have observed coming to your works, and during how many hours has this continued?—Our storm overflows are set to deliver 4,200,000 gallons per 24 hours. This rate has been recorded continuously for 11 hours.

21070. What storm overflows have you on your sewers, and at what rate or rates of flow do they come into operation?—No storm overflows are fixed on the sewers. The whole of the storm water is conveyed to the entrance to the sewage works, where a half-inch primary screen is fixed, cleaned by revolving rakes. The grosser solids are thus arrested before the storm water passes over the storm overflows to the river. This storm overflow comes into operation at six times the average dry weather flow, *i.e.*, 4,200,000 gallons.

21071. What is the largest number of gallons of sewage which have passed the storm overflow and come to your works in 24 hours?—3,573,000 gallons.

21072. Can you say what is the volume of water in gallons represented by the average yearly rainfall on the drainage area?—Yes; 362,008,000 gallons.

21073. Can you give the Commission an approximate statement as to the volume of sewage which comes to your works during the year, and the volume which passes over your overflows?—The volume which comes to the works is 394,025,000 gallons. No continuous gaugings have been taken as to the amount of sewage passing over the storm overflows. Gaugings during very heavy rain have registered at the rate of 30,000,000 gallons per 24 hours. These flows have not been of long duration. The rainfall on the drainage area, plus the water supply, equals 533,558,000 gallons; deduct 394,025,000 gallons delivered at the sewage works, leaves 139,533,000 gallons as having passed to the river.

21074. Does the infiltration of subsoil water into your sewers occur regularly, or does it vary with the seasons or with the state of the weather; and can you give an approximate idea of the extra amount of liquid at one and another time entering the sewers from this source?—It does not occur regularly, but differs according to the state of the seasons and weather. The only means I have of gauging this inflow is by comparing the low night flows in summer and winter. From these figures I get an excess in winter over summer of 99,000 gallons per 24 hours.

21075. How many gallons of trade effluents enter the sewers daily (24 hours), and what is the nature of these effluents?—About 70,000 gallons per day. This consists of brewery, dye, tannery, and fellmongers' waste. No analyses have been obtained owing to the manufacturers having free access to the sewers.

21076. Has your authority framed any rules as to the reception of trade effluents into the sewers?—No.

21077. Do you find that the trade effluents interfere with the process of purification by reason of their quality, variations in composition, fluctuations of volume or otherwise? If so, would you kindly tell us what your difficulties are?—Trade effluents of the nature we get do not interfere materially with the treatment when delivered in a regular stream. In the case of one or two manufacturers their wastes are turned into the sewers at intervals in large volumes. There is then a difficulty in treatment owing to the precipitant not being regulated to the increased strength and volume of the sewage.

21078. In dry weather what is the average amount of suspended matter in the sewage, and what are the highest and lowest figures in parts per 100,000?—The average amount of suspended matter in dry weather is 29 parts per 100,000. The maximum amount is about 46 parts per 100,000; during the night it has fallen

as low as 6 parts per 100,000. These figures do not include the screen refuse and the grit, etc., which settles in the "catch pits."

21079. What is the physical character of these solids?—The solids consist of large numbers of cotton fibres, fat, insoluble soaps, small particles of paper, excreta, etc.

21080. Can you give average analyses of the sewage for the years 1903 and 1904 in summer and in winter?—Yes, the analyses are as follows:—

	1903.		1904.	
	Summer.	Winter.	Summer.	Winter.
Oxygen absorbed 4 hours' test	8·32	6·73	8·66	7·86
Ammoniacal nitrogen	3·23	3·19	3·52	3·51
Albuminoid nitrogen	·63	·86	1·03	·80
Chlorine	7·9	6·4	8·3	7·2

21081. Is it a "strong" sewage, and, if so, what characterises its strength?—From the foregoing analyses I consider the sewage to be a fairly strong domestic sewage. I judge the strength of the sewage on the albuminoid nitrogen and the oxygen absorbed figures.

21082. Does its strength vary very much from hour to hour or on different days of the week, and, if so, do these variations affect the quality of your final effluent to a marked degree?—The sewage varies considerably from hour to hour, as shown by the Diagram No. 1 on the oxygen absorbed test. We do not get a tank effluent which varies in the same degree. Taking the flow from day to day there is a varying strength on various days, Mondays and Tuesdays being the worst; this fluctuation is noticeable also in the subsequent effluents, as shown in the Diagram No. 2. (*See* Diagrams at end of Mr. Bolton's evidence.)

21083. How do you think "strength" of sewage, as affecting purification, is best expressed or measured?—In my opinion the strength of the sewage is given best on the albuminoid nitrogen and oxygen absorbed figures.

21084. Have you any information as to the bacteriological condition of the sewage?—No.

21085. Are there any chemical poisons in the sewage?—No.

21086. Is the sewage always alkaline?—Yes.

21087. Do you find that the amounts of suspended solids are increased or diminished in times of storm; and can you give the Commission the figures at the end of each hour during a storm of some hours' duration?—The suspended solids are greatly increased in times of storm. The following figures were obtained during heavy rain lasting four hours:—

First rushes	238	parts per 100,000
After one hour	110	,, ,, ,,
After two hours	69	,, ,, ,,
After three hours	50	,, ,, ,,
After four hours	38	,, ,, ,,
After five hours	33	,, ,, ,,
After six hours	28	,, ,, ,,
After seven hours	18	,, ,, ,,

21088. How many years ago were your sewers laid, and do you know whether they have sunk much in places so as to allow solids to accumulate?—Thirty-five years. There are a number of places where the sewers have sunk, and accumulations do occur, and are washed to the sewage works in times of storm.

21089. What is the character of the liquid part of the sewage in storm times? Perhaps you could illustrate this by analyses of the liquid portion in dry weather and in storm times?—The liquid part of the sewage for the first two hours is very foul. If the storm is of long duration the liquid gradually gets weaker. The following figures show analyses of (a) the liquid part of the sewage, (b) the liquid part after two hours storm flow, and (c) after five hours storm flow:—

	(a)	(b)	(c)
Oxygen absorbed (four hours' test)	5·80	3·20	1·62
Ammoniacal nitrogen	1·65	2·70	1·19
Albuminoid nitrogen	·39	·24	·10
Chlorine	8·3	7·4	4·9

21090. In what way or ways do you think the sewage which comes to the works should be dealt with in storm times? Perhaps I should amplify this question a little. The usual requirements of the Local Government Board are, I understand, that any increase in flow up to three times the normal dry weather rate should be fully dealt with by the ordinary complete plant, and that a certain number of additional dilutions—up to a total of six—should be treated on special storm filters. Do you think these are proper requirements, or do you think they should be modified in any way? It is, I believe, often found that the storm sewage which first comes down to the works contains a largely-increased amount of suspended solids, and I should like to know whether you consider that your ordinary (dry weather) plant is exposed to damage in any way—as, *e.g.*, rapid choking—by having to deal with this amount of storm sewage, and whether you think it would be better to adopt some other treatment. Although the storm sewage, including the suspended solids, is a very polluting liquid, possibly the liquid portion alone is not very polluting, and this suggests that settlement of all the sewage arriving at the works in time of storms in tanks for a few hours, after, possibly, the addition of chemicals, might perhaps be a better plan of treatment than passing a portion of it through the ordinary plant, and the balance through storm filters. Would such settlement alone be sufficient for the whole of the sewage arriving at the works in times of storm? I should be glad if you would state your views fully on this question and if you would also tell the Commission what number of dilutions you think it practicable to treat in one or another way?—At Heywood we have endeavoured to treat our storm water in accordance with the requirements of the Local Government Board. Three times the dry weather flow being passed through the tanks, and from three to six times the flow dealt with on special storm filters. In my opinion this method is not the most satisfactory, either to the local authorities or to the conditions of the rivers. I find that admitting three times the dry weather flow to the tanks brings about a serious condition in the tank effluent. Not only is the effluent at first composed of partly settled sewage, but the sludge in the tanks is disturbed, and in the course of two or three hours after the storm flow has reached the works the tank effluent is in a worse condition than the in-coming sewage. The effect of passing this effluent on the filters is almost ruinous. The whole surface of the filters (contact beds) becomes coated with a layer of fine mud, which requires removing at considerable expense before the ordinary volume can be passed on the bed, the sludge interfering with the free passage of the liquid. In our storm filters provision is made for treating 500 gallons per square yard. There is a cast-iron distributing trough down the centre of the beds. When the storm water reaches the troughs it flows over the sides and down through the cinders to the effluent drains until the surface becomes choked. The water then flows over the choked surface to the free portions of the bed, thus gradually choking the whole areas of the beds. The surface of our beds become choked at the rate of 355 square yards per month when dealing with a storm flow on a dry weather flow of 500,000 gallons per day. The flow through storm filters is extremely rapid, owing to not being evenly distributed over the bed. The following are

Mr. Joshua Bolton.

10 May 1905

average analyses after the first rushes of a storm: (a) Storm sewage two and a-half hours after storm commenced, (b) same sewage after being settled two hours in a tank, (c) storm filter effluent 20 minutes after sampling (a):—

	(a)	(b)	(c)
Oxygen absorbed (four hours' test) - -	5·00	3·20	3·66
Ammonical nitrogen -	1·84	1·55	1·64
Albuminoid nitrogen -	·56	·37	·56
Chlorine - - -	4·8	4·5	4·6
Suspended solids - -	61	16	23

The two hours settlement gave a better result than the storm filters. I consider a good plan of dealing with storm water would be to pass only twice the average dry weather flow through the ordinary tanks, and from two to six times through special settling tanks having a capacity equal to a six hours' flow. I think a portion of the effluent from these tanks could be passed through percolating filters more rapidly without doing damage than could an effluent from the ordinary dry weather tanks when worked at the rate of three times the dry weather flow. Though the increase in volume should be obtained by decreasing the intervals of rest between the discharges rather than by turning it on in excessive volumes. A great saving could be effected by collecting the sludge from the storm water in tanks, and dealing with it along with the other sludge rather than by collecting a portion of it on storm filters and skimming it off by manual labour.

21091. What shape and size are your storm overflows?—Our first overflow is in the form of a leap weir 8ft. long. A half-inch primary screen is fixed in front of the overflow so that the grosser solids do not go to the river. This does not work very satisfactorily. Another overflow is fixed on the weir principle, which passes any excess (which has passed the leap weir) on to the river. These sills are 4ft. 6in. long.

21092. Would it be possible to have a standard form of overflow, and how would you fix the point at which overflows should be allowed to come into operation?—I think a good form for a standard overflow would be one with a long sill and two or three baffle plates fixed at right angles to the sill. Whatever number of dilutions are decided on, the sill and baffle plates should be fixed so that the baffle plates would turn the excess water either to the river or storm tanks as the case may be. This arrangement could be easily arranged for either fixed or movable overflows.

21093. Do you think that the point at which storm overflows should come into operation should depend on the configuration of the land, *e.g.*, whether it is hilly or flat, etc., and upon the character of the surface soil geologically?—I do not see how it would be possible to arrange a fixed overflow to suit varying conditions. The first rushes of storm water in a hilly district bring down large quantities of solid impurities which ought to be intercepted. However, if the storm overflows were fixed high to intercept it, a large volume of weak sewage would unnecessarily be passed on to the works, and would probably push out the partly-settled strong storm water at the other end.

21094. Should storm overflows be fixed or movable?—If storm overflows were movable some of the difficulties would be overcome. The possibility of misuse would be a strong factor against movable overflows. Under sound and reliable control a movable overflow would be most satisfactory for general conditions.

21095. Do you think the number of dilutions at which storm sewage may properly be allowed to pass into the stream should be dependent upon the size and nature of the stream into which the storm sewage would pass? Is it possible, for example, that in some circumstances no injury to the stream would be caused by allowing overflows to come into operation when the increased flow was slight, while in others this would not be the case?—It may be possible in towns on a tidal river to allow the storm overflows to come into operation at a less number of dilutions than inland towns. I do not think there are any rivers which do not suffer from the first rushes of storm water, though naturally the tidal rivers will not suffer to the same extent as the inland rivers. My experience on a river of 30 times the volume of the inflowing sewage effluent is that the river becomes seriously polluted during the first rushes of storm water.

21096. Could you give us an analysis of a typical sample of your road water during the early period of a storm?—Yes. A sample of road water taken in principal streets during first rushes of storm gave the following analysis:—

Oxygen absorbed in 3 minutes - -	12·50	
Oxygen absorbed in 4 hours - -	19·90	
Ammoniacal nitrogen - - - -	1·11	
Albuminoid nitrogen - - - -	·49	
Chlorine - - - - - -	8·7	
Suspended solids, vol. - - - -	25	
Suspended solids, non-vol. - - -	59	=84
Solids in solution, vol. - - -	22	
Solids in solution, non-vol. - -	51	=73
Total solids - - - - - -		157

21097. Have you any information as to the bacteriological condition of the road water?—No.

21098. Do you consider that in certain circumstances the road water should be purified?—I consider that road water should have some form of rough treatment, such as settlement in tanks, before being passed into a stream.

21099. What are your views as to the comparative cost and advantages of the separate and combined systems of sewers?—I have not had any experience with the separate systems of sewers.

21100. Is your sewage settled, and, if so, how?—Our sewage is settled after the addition of chemicals.

21101. Do you prefer to use precipitation tanks in series or in parallel?—I prefer to work the tanks in parallel, thus getting a divided quantity of sewage in each tank, and consequently a more gentle flow through the tanks.

21102. In the case of continuous flow tanks, do you think there is any advantage in the employment of baffling boards or walls?—I do not find much to be gained by baffling walls. I have tried both methods—that is, with and without—and did not find any benefit from the walls. They were a source of considerable inconvenience during sludging operations. Scum or fat boards at the outlet end I find very effective in keeping the floating matter from passing on the filters.

21103. How is the sludging of tanks done at your works? Have you means of storing sludge, or do you have to get rid of it as soon as it is removed from the tanks?—The sludging at our works is done in two methods. Two tanks have Candy's travelling sludge removers erected in them. These work by a syphonic action, and deliver the sludge into a deep channel running between the two tanks, which is connected to the sludge culvert. After the syphon has been started the machine is made to travel along racked rails (upon which it is mounted) by means of pinion gearing actuated by hand. This method has the advantage of the tanks not being run off for sludging operations. A large quantity of water is brought over by the apparatus, and the tanks are not nearly so well freed from sludge as are the other four tanks, which are sludged by means of running as much liquor off as possible and then sweeping the whole of the sludge out of the tanks. With care it can be arranged that the tank previously sludged can be filling during the period the next tank is being run off for sludging, and thus preventing any extra rush being turned on the filters. We have one day's storage capacity.

21104. Should the heavy (road detritus, etc.) portion of the suspended matter in sewage be removed as a first operation, or do you think it better and more economical to let everything settle in the tanks, and subsequently to screen the sludge?—It is far better to remove the heavy road detritus as a first operation, particularly where the sludge has to be pumped after being removed from the tanks. The grit from the road surfaces has a very serious effect on the brass plungers and valves in the pumps. In cases where no pumping is required I still think it advisable to remove the road detritus as a first operation, as this matter in times of storm is of great bulk and settles in the tanks an inert substance, and rapidly diminishes the capacity of the tanks.

21105. You have had experience of chemical precipitation of sewage?—Yes.

21106. Have you any reason to think that sewage from which the solids have been removed by the aid of chemicals is less easily purified by subsequent filtration than sewage from which the solids have been removed by settlement or by passage through septic tanks?—My experience at Heywood has been that a chemically treated sewage was more easily treated in the contact filters than a sewage treated in a septic tank.

21107. Have you tried various chemicals? Can you give any comparative data on the practical value and cost of different precipitants for the preliminary treatment of sewage, stating whether you are referring to the precipitation of strong or of weak sewage?—I have tried various chemicals. Iron and alumina compounds have been used under such trade names as alumite, kremnolite, ferrozone, aluminoferric, etc. Aluminoferric is the best precipitant tried at Heywood. With an addition of 8 grains per gallon a purification of 62 per cent. is brought about. This equals £1 7s. 6d. per million gallons. Ferrozone under the same conditions brought about a purification of 57 per cent., equal to a cost of £1 6s. 6d. per million gallons. Thus for 3·6 per cent. reduction in price 8 per cent. less purification was obtained by ferrozone.

21108. What is the most effective way of adding chemicals?—In solution of known strength.

21109. What is the average analysis of the liquor from your precipitation tanks? What length of time does the sewage remain in the tanks?—The average analysis is as follows:—

Oxygen absorbed (4 hours' test) - -	3·38
Chlorine - - - - - - -	6·7
Ammoniacal nitrogen - - - -	1·99
Albuminoid nitrogen - - - -	·42
Nitric nitrogen - - - - -	Traces
Suspended solids - - - - -	4·0

An effluent containing as low as 2 parts per 100,000 is often obtained. When storm flows are turned through the tanks the suspended solid figure gets as high as 25 parts per 100,000. The rate of flow in dry weather is 24 hours.

21110. What is the character of the suspended matter in such liquor?—The suspended solids consist of broken cotton fibres, insoluble soaps, small particles of the precipitate, aluminium hydrate, and gelatinous albuminoids, which give a cloudy appearance to the effluent. In times of storms fine particles of clay, straw, etc.

21111. Do you find it necessary to add further chemicals to the sludge before it can be dealt with? If so, for what reasons, and what chemicals do you use, and how are they added?—We find it necessary to add a small quantity of lime to the sludge to keep it porous and to prevent it sticking to the sheets. The quantity added is 1·2 per cent., and it is mixed just previous to the sludge being passed into the ejectors.

21112. What is the manurial value of the sludge obtained by the chemical precipitation of the sewage at your works, and will farmers take it?—The manurial value of the sludge is good. It is all taken by local farmers, and large crops are raised from it. It contains on analysis:—

Moisture - -	56·23
Organic matter -	19·95
Mineral matter -	23·82
	100·00
Nitrogen equal to	·95 of ammonia.
Phosphate of lime	1·44

21113. Do you find any nuisance from the treatment of sewage in chemical precipitation tanks? Have any complaints been made?—The smell from the tanks is only offensive during sludging operations. There are no dwellings near, and consequently no complaints have been made.

21114. As regard septic tanks, how should they be shaped?—Rectangular, length about four times the width.

21115. Should they be divided into sections?—Not in the tank proper. When not preceded by catch-pits, a grit chamber should be built at the inlet end, which could be cleaned without disturbing the tank.

21116. Should they be used in series or in parallel?—In parallel.

21117. Is a scum necessary or desirable?—I do not think scum is absolutely necessary, but it is desirable. A scum has the advantage of keeping the smell down, and, further, keeps the lighter solids over the whole surface, and thus prevents them being washed out of the tanks before they have been resolved into simpler compounds.

21118. Should the septic tank be closed in, and, if so, what advantages does a closed tank possess over an open one?—I do not think a septic tank need be covered when a fair distance from any dwellings, but should dwellings be near it would be a good plan to cover the tank and thus avoid nuisance from smell.

21119. What do you consider the best arrangement for the "feed" and "draw-off"?—Dibbing inlets and bent outlets, as shown in the sketch below:—

21120. At what rate is sewage, as a matter of custom, passed through your septic tanks?—At the rate of the dry weather flow of 24 hours.

21121. What is the most advantageous rate of flow through septic tanks, and what is the rate of flow at which quicker passage through the tanks becomes, in your opinion, distinctly disadvantageous? Do you think that the rate of flow should depend on the strength or character of the particular sewage which is being dealt with?—I consider the best method of working septic tanks is to have the tank liquor coming away as uniform as possible, and to get this, with either a weak or strong sewage, the tank should have a capacity equal to 24 hours' dry weather flow. In this manner we get the varying strengths mixed as far as practicable, and a fairly even flow going on to the filters. My experience is that when the flow is increased up to the rate of three times the dry weather flow the sludge which has settled in the tank is disturbed, and portions pass over with the tank liquor, which is decidedly disadvantageous.

21122. Is it possible to "over-septicise" a sewage, and, if so, for what reasons, and how is the "over-septicising" brought about?—It is possible by too slow-working of septic tanks to get the effluent giving off very offensive odours of sulphuretted hydrogen.

21123. What is the amount of digestion in your septic tanks, and how do you calculate this?—My experiments were conducted in a small tank not suitable for making calculations as to digestion. A large tank is now at work which will shortly be available for calculations. The amount of digestion I should calculate from the solids in the sewage minus the solids in the effluent plus the sludge.

21124. Do you think a certain amount of sludge should be removed periodically from septic tanks, or do you prefer to work them for a considerable period without cleaning and then remove all the sludge?—I find it better not to take small portions of the sludge out of the tanks at short intervals, as this disturbs the tank, and it is necessary to allow time for settling. I find it better to let the tank run a fair length of time and then remove all the sludge.

21125. How often would you clean out the sludge?—Circumstances would have to govern the period of cleaning. I should not let the tank get half full of sludge; when it was approaching this I should empty it.

21126. How do you think the sludge should be taken out of the tank, and how should it be disposed of? Does any nuisance attend the operation?—The sludge should be removed by drawing as much water off as possible, and then passing the sludge through a pipe at the bottom of the tank, to be dealt with in the sludge presses, and afterwards burned. A very offensive smel is given off, which would no doubt be a nuisance if dwellings were near.

21127. Do you find that the suspended solids coming away with the tank liquors tend to increase in amount towards the end of the period of working, *i.e.*, as the time approaches for removing sludge from the tank?—Yes.

21128. What amounts of suspended solid, stated in parts per 100,000, are contained in your septic tank liquor at the commencement of the period of working the tank, *i.e.*, just after the tank has been cleaned out, and at the end of period, *i.e.*, when the tank is thrown out of use for the purpose of cleaning out, and what is the average amount?—In the small tank the solids were not determined, but the increase was very perceptible in the appearance of the samples. In some samples I examined from a neighbouring authority the solids in suspension, after starting, averaged 3 parts per 100,000. A number of samples examined when the tank had been working six months contained 9 parts per

Mr. Joshua Bolton.

10 May, 1905.

100,000 of suspended solids. The sewage is of a weak character.

21129. Should any portion or the whole of the sewage which arrives at the outfall works in storm times be passed through the septic tanks?—I do not find it advisable to pass storm water through septic tanks at a greater rate than twice the average dry weather flow.

21130. If storm sewage is passed through a septic tank, does this cause an increase in the amount of suspended solids issuing from the tank, and, if so, can you give us figures (in parts per 100,000) showing what the increase is?—Yes. A considerable increase in the amount of suspended solids takes place when storm sewage is passed through the tanks at the rate of three times the dry weather flow. The suspended solids have increased up to 38 parts per 100,000 in times of storm.

21131. Have you made any observations as to the effect of raising the ordinary level of the liquid in a septic tank through the admission of storm sewage or the use of automatic gear?—Our tanks would not permit of the level being raised, and I have therefore not been able to try this method.

21132. Do you find that septic tank liquor is more easily treated on filters than settled sewage or than precipitated sewage, assuming that in each case you have the same amount of suspended solids in your tank liquor?—In practice at Heywood I do not find that septic tank liquor is more easily treated than precipitated sewage. We get on an average 64 per cent. purification in the filters treating precipitated sewage, whilst the filters treating septic tank liquor gave only 53 per cent. The suspended solids in the septic tank effluent were more abundant than the solids in the precipitated effluent by appearance. The suspended solids were not regularly determined during the experiments.

21133. Are the impurities in solution in sewage materially different from the impurities in solution in septic tank liquor?—I have no data.

21134. Have you any data on the relative value of plain septic tanks and septic tanks filled with rough stones or flints?—No.

21135. Do you find any nuisance from the treatment of sewage in septic tanks? Have any complaints been made?—A very offensive smell is given off, and if houses were in the near vicinity I think complaints would be made.

21136. Do you think it desirable that the suspended solids in sewage should be removed as far as practicable before sewage is filtered? If so, what do you consider a practicable limit to get down to?—I think it is essential that the solids in sewage should be removed as far as practicable. The practicable limit would be lower in a chemically treated sewage than in a septic sewage. Four parts per 100,000 could be attained in a chemically treated sewage, whilst 8 parts per 100,000 should be aimed at for septic tank effluents.

21137. What, in your opinion, is the best way of removing suspended solids?—A well-constructed tank with suitable inlets and outlets ought to answer.

21138. Have you any experience of any mechanical device or any special tanks for freeing tank liquor of suspended matter before delivering it to filters?—I have no practical experience of either mechanical arrangements or special tanks. The solids in the tank effluent could be reduced very considerably by means of a mechanical filter, or centrifugal action in tanks. The expense in the first method and the head required in the second method would be great disadvantages.

21139. What other (if any) method of dealing with tank liquor before delivering it to filters do you regard as necessary or desirable?—I do not think any further treatment is necessary before being delivered to the filters.

21140. May I ask you to put before the Commission a full statement of your views as to the comparative cost and relative advantages of the various methods of settlement. I am not sure whether it would be possible for you to make this comparison on the assumption that in each case you reduce the same sewage down to the same figure for suspended solids, but if this could be done it would be useful to include a comparison on this basis. In framing your answer, please take into account the question of nuisance, the subsequent dealing with the sludge, the subsequent purification of the tank liquors, and the annual cost as well as the initial expenditure. It may be that with some kinds of sewage you would prefer one method and with other kinds another. If so, perhaps you would kindly indicate what rules you think should determine the choice?—My experience is limited on this question. I have only had experience with quiescent settlement with chemicals, continuous flow settlement with chemicals, septic tank treatment. The sewage has been treated as it has arrived at the works, irrespective of the result—that is to say, no extra period of settlement has been given to reduce the suspended matter to one figure. In actual practice this is not possible. As regards quiescent settlement: In this method the same amounts of chemicals were used as in the continuous settlement. A slightly better result on the average was obtained. The disadvantage of the system was that more attention, and consequently extra labour, was required. Secondly, the effluent was not at all even. The tank which received the night flow when run off was exceptionally weak, and the tank which received the day sewage was correspondingly strong when run off; in fact, we got almost the same degree of variation as appeared in the incoming sewage. The equalisation of continuous settlement was lost and extra labour required. As regards continuous flow settlement: This method did not give quite so good results as the quiescent settlement, but the effluent was more uniform and the labour less. The percentage purification was 62, and the cost of filtering was about equal. As regards septic tank treatment: In this form of treatment the tank purification is only 36 per cent., against the above 62 per cent. Considerable saving is affected in chemicals, which will in Heywood amount to £353 per annum. We calculate a further saving of nearly one-half the sludge pressing. In the case of septic treatment double contact beds were required to get an effluent as satisfactory as a chemically precipitated effluent and one contact. So whilst a saving in chemicals is effected by septic tank treatment, the area of beds to be constructed would be increased in the proportion of 100 for chemical precipitation and 166 for septic tank treatment.

The following is the annual cost at Heywood for the three systems, contact beds being used in all cases:—

	Continuous Flow Settlement.	Quiescent Settlement.	Septic Tanks.
	£ s. d.	£ s. d.	£ s. d.
Cost per annum for sludge pressing	662 16 2	662 16 2	340 0 0
Cost per annum for chemicals and labour	821 6 3	854 13 7	—
Cost of labour in attention and sludging	—	—	381 6 0
Interest and sinking funds on capital expenditure	1,317 0 4	1,317 0 4	1,533 5 0
	2,801 2 9	2,834 11 1	2,254 11 0

The double contact bed did not work long enough to make a calculation as to the period of sludging up. The risk of nuisance is greater in septic tank treatment.

21141. As regards contact beds, is it advisable to construct the whole or any part of the interior of building materials, or may you in some cases dispense with this entirely?—It is advisable to construct contact beds

of building materials when the site is limited, but where the area of the site is unlimited, and the levels are such as would permit the beds being excavated out of good ground, *e.g.*, clay, then it may be advisable for economy to construct them without walls; but in all cases I think some impervious material should be placed in the bed to prevent the soil being worked up into the filtering material.

21142. Do you find that within certain limits the depth of contact beds may vary without affecting their efficiency? If so, what limits do you think are permissible?—I think a bed should not be more than four feet in depth, for I find that the rate of purification is not so rapid at and below this depth as in the upper layers of the bed.

21143. What do you consider is the most convenient size for a contact bed?—From one-ninth to one-twelfth the units; so that if a bed is thrown out of use for a rest it should not put so much area out of use.

21144. What do you find to be the best filtering materials? What is the material (which can be had in practicable quantity) that, while efficient, is in your experience the least disintegrable in a contact bed?—Gas coke gave slightly better results than clinker in our experiments, but it had a greater tendency to fall. In our district well-burned furnace and destructor clinker is the best material, which can be got in bulk.

21145. What size should the filtering material be, and should it be graded in the beds?—The sizes we found to work well were, for first contact beds, to pass 1½-inch mesh and be rejected by ½-inch mesh; second contact beds, to pass ½-inch mesh and be rejected by ¼-inch mesh. I don't think the material should be graded in the beds. It is advisable to place a small quantity of fine material near the inlet troughs; by this means a large quantity of suspended matter is prevented from entering the bed.

21146. How should the bottom of the bed be constructed?—Of impervious material, slightly inclined towards the outlet, and well drained with perforated pipes.

21147. Do you think it generally desirable that sewage should be subjected to some form of tank treatment before it is put on contact beds?—Yes.

21148. What periods of filling, standing full, emptying, and standing empty do you consider best in practical working for primary beds and for secondary beds?—The most satisfactory results were obtained on the first contact beds by the following periods: One hour filling; two hours full; half-hour emptying; four and a half hours resting. The second contact beds were worked at the following rate, being of the same size as the first contact beds: Half-hour filling; two hours full; half-hour emptying; five hours resting.

21149. How should contact beds be filled and emptied?—Under personal control.

21150. If you have had experience of automatic gear for filling and emptying contact beds, would you kindly give your views of such gear?—I have not had any practical experience of automatic gear for working filters. On our beds I fixed electric contacts, and by this means a large bell was rung when the bed was nearly full, thus saving constant attention and overfilling of the beds.

21151. What amount of tank liquor per cubic yard of filtering material can, in practice, be properly treated in a primary contact bed in 24 hours? If the amount varies with the quality of the tank liquor, please state by analytical figures what quality of tank liquor you are assuming in your answer, and how differences in the tank liquor affect the amount that can be properly treated?—I found that three fillings per day, equalling 100 gallons per cubic yard, with a septic tank liquor containing ·35 parts of albuminoid nitrogen, and absorbing 5·25 parts of oxygen in the four hours test, gave a percentage purification of 50 on the oxygen figure, and ·36 on the abuminoid nitrogen. I don't see how in actual practice it would be possible to give a variable contact with various strengths of sewage, as the sewage has to be dealt with as it arrives at the works, and the strength is highest when the flow is highest.

21152. What amount of liquid from a primary bed can in practice be properly treated on each cubic yard of filtering material of a secondary bed in 24 hours?—About 1½ times the quantity treated on the first contact bed.

21153. Can these quantities be increased by more frequent filling and emptying in times of storm without impairing the efficiency of the beds or the quality of the effluents?—Yes, with storm water proper, provided the suspended solids have been considerably reduced. The storm water should be passed through the beds at the same time as the weak storm effluent from the septic tanks. The tank liquor which comes out of the tank when storm water is admitted is very strong for the first few hours, and this could not be passed through the bed effectively at a quicker rate.

21154. Is one contact sufficient for the conversion of certain tank liquors into a satisfactory effluent? If so, please state in precise terms (*i.e.*, by analytical figures) of what tank liquors you are speaking, and what effluent you are regarding as satisfactory?—I think one contact is sufficient for weak tank liquors from Sunday sewages or a well-settled storm water where the four hours oxygen absorbed figure is as low as 2·5 parts per 100,000 and the albuminoid nitrogen ·20. These figures could be reduced by one contact down to 1 part for the oxygen absorbed figure and about ·1 for the albuminoid figure, which I should consider a satisfactory effluent.

21155. At what rate or rates do primary contact beds and secondary contact beds lose their water-holding capacity?—At the commencement our primary beds had a capacity of 49 per cent., and the secondary beds 50 per cent. After working 40 weeks and receiving 720 fillings the capacity of the primary bed was 32·2 per cent. and the secondary bed 34·5 per cent. In the single contact beds treating the chemically precipitated effluent the capacity remains fairly constant. Rough measurements have been made from time to time by means of a weir, the capacity being about 32 per cent. Careful actual measurements were made on October 13th, 1902. After working four years and ten months and receiving 3,972 fillings the capacity was then 34·42 per cent. The last actual measurement was made on March 22nd, 1905, after working six years and three months and receiving from the previous actual 2,420 fillings, or a total of 6,392 fillings since bed commenced, the capacity was then 31·9 per cent. The following is an analysis of the liquor which was being treated:—

Oxygen absorbed, four hours' test	3·38
Chlorine	6·7
Ammoniacal nitrogen	1·99
Albuminoid nitrogen	·42
Nitric nitrogen	Traces.
Suspended solids	4·0

21156. What causes the loss of capacity?—With our beds treating the precipitated sewage the loss of capacity is due to the gelatinous growth on the material. This grows fairly regularly when the usual volume of water is treated. The capacity can be restored by resting the bed. With the beds treating septic tank liquor the diminution in capacity was more rapid, and did not regain its capacity to the same extent, proving that the loss of capacity is due to the solid matter which is passed on the bed.

21157. Can the material of a clogged bed be washed, and, if so, how can this best be done, and at what cost per cubic yard?—I have tried to wash the beds by means of a current of water turned in an upward current through the bed, using the effluent from the other beds. This was not satisfactory, as the head available was not sufficient. The best method I know of is to remove the material from the beds and pass it through a revolving screen along with a supply of water. It is said that this method costs 1s. per cubic yard, but I think 2s. would be nearer the mark.

21157*. How can the capacity of contact beds be best maintained?—By giving regular periods of rest and by placing a layer of fine material at the top of the beds, and replacing this as it becomes choked.

Mr. Joshua Bolton.

10 May, 1905.

21158. What is the average analysis of your single contact effluent and of your double contact effluent?—The average analyses are as follow:—

	First Contact.	Second Contact.
Oxygen absorbed 4 hours' test	2·69	1·08
Chlorine	7·4	7·2
Ammoniacal nitrogen	·93	·49
Albuminoid nitrogen	·19	·10
Nitric nitrogen	Occasional traces	·61
Putrescibility	All	7·20
Solids	Not determined	

21158*. Can you state the number of gallons of liquid treated daily per cubic yard of filter material in your first bed, and the number of gallons treated daily per cubic yard of filter material in the two beds?—Yes; 170 gallons per cubic yard on the first contact bed or 85 gallons per cubic yard on the combined beds.

21159. Do you find any chemical poisons in your final effluent?—No, judging from the action on fish life.

21160. What is the average amount of suspended matter in the effluents? Does most of this come out with the first flush or not?—During the experiments suspended solids were not regularly determined. The first rushes always contained the greater proportion of suspended solids.

21161. To what extent do you find that the organic matter of the suspended solids issuing in the effluent from a contact bed is different from the organic matter of the suspended solids going on to that bed?—I do not find the proportion of the organic to inorganic matter to vary much in the solids going on a bed and the solids leaving the bed. I generally find solids going on the bed to contain about 3 per cent. more organic matter than the solids leaving. The solids leaving a bed are granular in appearance, and settle quickly; the solids going on the bed do not settle rapidly, and are more gelatinous in appearance, and keep in suspension and give a cloudy appearance.

21162. Is the first flush of effluent from either set of beds ever putrescible?—Yes.

21163. Do you find that by increasing the number of fillings in storm times or other times the amount of suspended solids is increased?—Only slightly.

21164. May contact beds in times of storm be used as streaming filters without detriment to their customary efficiency, and, if so, do you think there are advantages in so working them?—I do not think there is any advantage in using a contact filter as a streaming filter in times of storm. The whole of the bed is not brought into use, and there is a great tendency to choke the beds near the inlet.

21165. What was the cost of your contact bed installation per acre, and how much liquid do you treat per acre per 24 hours in ordinary times and in storm times. Please state whether you have single or double contact, and what is the depth of your beds?—Our single contact beds are constructed very elaborately, and the cost works out at £21,240 per acre, but only 1,340 square yards are constructed. We treat the tank liquor at the rate of 822,800 gallons per acre. We do not attempt to pass more than 1,097,000 gallons per acre through in times of storm. The beds are 3 ft. deep.

21166. Have you made any experiments which throw light upon the action of contact beds when full and when resting?—The observations I have made in regard to the action of contact beds have been with various lengths of contacts, the rate of purification at various depths of the bed, and also running the tank liquor through the beds immediately after the bed has been discharged and after it has had its usual period of resting empty. The following are averages of some analyses under the above conditions:—

	Tank liquor.	Continuous flow after filter has been run off.	Continuous flow after filter has had period of rest.
Oxygen absorbed (4 hours test)	2·00	1·31	0·87
Ammoniacal nitrogen	2·29	1·95	1·15
Albuminoid nitrogen	·42	·28	·26
Nitric nitrogen	Nil	Traces	·77

21167. Have you made a study of the conditions of aeration of contact beds?—No.

21168. Do you find any nuisance from the treatment of sewage on contact beds? Have any complaints been made?—I do not find any nuisance whatever from the treatment of sewage on contact beds.

21168*. As regards continuous or percolating filters, what do you find are the best filtering materials, and what size should the material be?—Well-burned destructor and furnace clinker of size from 4in. to 2in.

21169. What depth should a percolating bed be to obtain a good effluent? If this varies with the quality of the liquid going on, or with the size of the filtering material, please state how it varies, what depths you require for different liquids, and how you would distinguish one liquid from another, *i.e.*, what analytical figures you would rely on for this purpose?—I have tried two depths of beds, one of 3ft. and one 8ft. The 3ft. bed was not satisfactory when dealing with a strong tank liquor, though with diluted tank liquors and weak Sunday sewages absorbing two or three parts of oxygen it gave an effluent which would satisfy the requirements of the Mersey and Irwell Joint Committee, but on ordinary days it was not satisfactory. With an 8ft. bed the effluent was always within the requirements of the Mersey and Irwell Joint Committee. For a weak liquor a less depth answers; say under three parts per 100,000 in the four hours' oxygen absorbed test and under ·2 parts per 100,000 of albuminoid nitrogen, a 3ft. would give a satisfactory effluent. In depths between three to eight feet I have not had experience with.

21170. Do you think it generally desirable that sewage should be subjected to some form of tank treatment before it is put on percolating filters?—Yes.

21170*. Is the material better disposed in the form of two beds, to be fed in succession with the same liquid, or in one deep bed?—The material is in my opinion better disposed of in one bed, particularly if the levels of the land are such that every inch is available. The collecting of the effluent and consequent redistribution of the liquid on the second bed would loose from 2ft. to 3ft. I tried two 3ft. beds in succession, and the effluent for a time was of a very satisfactory nature. Gradually the humus matter from the first bed formed an almost impervious layer on the surface of the second bed and prevented the free access of the liquid. The top layer was removed, washed, and replaced. In the course of a further three months the top had again become choked, and the experiment was given up. The conditions did not allow of a settling tank being fixed between the two beds.

21171. How should percolating filters be fed?—By means of sprinkling or spreading the liquid over the whole area of the bed.

21172. Should the feed be intermittent or continuous?—Intermittent.

21173. What is the best form of distribution? What, in your opinion, are the conditions which have to be fulfilled by a perfect distributor, having regard not merely to the distribution of the liquid itself, but also to the purification of the liquid and the life of the bed?—Revolving spreaders. They should deliver the liquid evenly over the whole suface of the bed, and should not be interfered with by either wind or frost. The sprinkler should work with a minimum of friction if the beds are to be kept in a healthy condition.

21174. Do you think it best to put on the filter a fairly constant amount of liquid, or do you consider that the amount can be increased in times of storm without impairing the efficiency of the filter or the quality of the effluent?—A filter could easily deal with a large volume of tank liquor in times of storm. I should not pass the liquor on at abnormal rates (say three times the dry weather flow), but should prefer to pass the liquor on at the usual rate, and arrange an apparatus which would bring more beds into operation, and whilst the storm lasted the beds would have a less interval of rest. If the storm water was dealt with, as previously mentioned, by a special tank, it could be so manipulated that whilst the filter had a larger volume of liquid to deal with, the total impurities would not be increased in the same degree.

21175. Is there any practical advantage in artificially heating the liquid which is being treated on percolating filters?—Assuming that the effluent from a bed artificially heated is slightly better than the effluent from a bed at ordinary sewage temperature, the increase in cost would outweigh any advantage gained, and would therefore not be a practical advantage.

21176. Have you had any experience to show whether open sides are an advantage to a percolating filter?—I have not made any experiments as to the value of open over closed sides, though, as the changes required are aerobic, it seems that open sides would be most suitable. Our new beds at Heywood are to be constructed with open sides.

21177. Have you made any study of the conditions of aeration of percolating filters?—No.

21178. What do you consider is the most convenient superficial area for a percolating filter?—This would be guided to a great extent by the amount of sewage delivered at the works. Care should be taken that the beds are not over large in comparison to the flow, so that if one bed has to be put out of action through accident or being sick the other beds should not be overburdened.

21179. Do you think it desirable that the bottom of a percolating filter should be raised from the ground?—Yes. It is very important that a percolating bed should be on a false floor, so that the humus matter can drop free from the filtering material, and thus be easily removed, otherwise the bottom layer of clinkers would become choked. The raised or false floor also gives better aeration to the lower portions of the bed.

21180. Do percolating beds, in your experience, choke?—I did not find that the single bed choked to any appreciable extent. After two months' working there appeared to be a fairly regular discharge of humus matter in ordinary times of working. When excessive volumes of water were turned on the bed it brought away large amounts of black matter. If choking did occur it suggests that by rushing a large quantity of water on the bed the material could be freed from these deposits which accumulate on the filtering material. As the material would not have to be removed for this operation, the cost of retreatment of the liquid would be the heaviest item of expenditure, and this would not be excessive.

21181. Of what nature are the suspended solids in the filter effluent? How much is organic matter, and are they putrescible apart from the liquid portion of the effluent?—The solids coming away from the percolating filter were granular in appearance, and settled fairly rapidly. They contained on the average

52·5 per cent inorganic matter
47·5 per cent organic matter.

The solid matter, apart from the liquid, upon incubation undergoes secondary decomposition in from three to five days at 80° F.

21182. To what extent do you find that the organic matter of the suspended solids issuing in the effluent from a percolating filter is different from the organic matter of the suspended solids going to that filter?—The organic solids issuing from the percolating bed are more granular in appearance than the solids on the bed. The solids settle more rapidly, and are not as glutinous in character as the solids going on the bed.

21183. Have you any experience of, or any suggestions to make on, the settlement or other separation of the suspended solids issuing from a percolating filter, and to what minimum figure do you think such settlement or other final treatment can be carried as a practical measure?—I conducted experiments with a view of ascertaining the amount of settlement required to get an effluent practically free from suspended matter. The greater portion had settled in two hours. In three hours there were only traces, whilst at the end of four hours the effluent was practically free from suspended matter. It is quite practical to obtain an effluent with suspended solids not exceeding 3 parts per 100,000.

21184. Do you find that the suspended solids in your filter effluent vary much in amount from time to time, and, if so, can you explain the causes of such variation?—During ordinary flows the suspended solids in the filter effluent appeared to be fairly even. When large flows were turned on the beds the suspended matter was increased, the large flow washing the sediment out of the bed.

21185. What was the cost of your percolating bed installation per acre, and how much liquid do you treat?—Our percolating bed was only an experimental one, and not suitable for calculating cost. The estimate for the twelve beds, 60 ft. diameter, 8 ft. deep, about to be put down, is £9,500 per acre. We propose treating 643,720 gallons per acre in dry weather and 1,936,000 per acre in 24 hours in wet weather as a maximum, though we never get this rate continuous for 24 hours.

21186. Have you made any experiments which throw light on the action of percolating filters with regard to the oxidation of the ammoniacal and organic matter in solution and the organic matter in suspension?—No.

21187. Have you evidence to show that ammonium salts and organic substances in solution, not of a colloidal nature, pass rapidly through a percolating filter, or that they are first absorbed by the filtering material or by growths on that material, so that their passage through the filter is a very gradual one?—No.

21188. Have you observed the effects of changes of atmospheric temperature on the working of a percolating filter?—I do not find the atmospheric temperature variations to have any great effect on the working of the beds. In frosty weather the temperature of the sewage averages 11° Centigrade.

21189. Have you found any trouble from vegetable growths in percolating filters? If so, have you been able to form any opinion as to the causes of these growths and as to the way in which the growths can be prevented?—When the supply to the beds was continuous a gelatinous mass grew on the surface of the bed. This was overcome by working the beds intermittently.

Mr. Joshua Bolton.

10 May, 1905.

21190. Do you find any nuisance from the treatment of sewage on percolating filters? Have any complaints been made?—The odour from a percolating bed is much more in evidence than the odour from a contact bed, and the risk of nuisance is greater. No complaints have been made, as dwellings are not near.

21191. Would you kindly compare the cost (initial expenditure and annual cost of upkeep and working) and relative advantages of percolating filters and contact beds? Do you consider that one form is best for some kinds of the sewage and the other form for other kinds of sewage?—I am of opinion that the percolating filter could be constructed at a less cost than double the area of contact beds with the necessary inlet and outlet channels, valves, etc. Some of the advantages a percolating filter has over a contact bed are that the upper layers of the filter do not become choked as soon as contact beds ; they are more easily cleaned, and, being more compact, they require less supervision ; more perfect distribution can be obtained ; and they can be worked more automatically. I find the percolating filter most suitable for our sewage, and for sewages generally.

21192. Do you find that the chance of nuisance is any greater with one form of filter than with another? Does the risk of nuisance depend on the kind of sewage which is being treated or on the nature of the preliminary treatment to which the sewage has been subjected? The question of nuisance is important, and I should be glad if you would state your views fully on these points?—The risk of nuisance does not depend on the kind of sewage or the preliminary treatment so much as the fact that in a percolating filter the liquor is delivered in the form of a number of small jets or sprays, therefore having a greater tendency to liberate any offensive gases or odours which the liquid may contain. If two similar liquids were passed on a contact bed in the ordinary manner, and on a percolating filter, there would be more odour given off from the percolating bed.

21193. Have you made any comparative observations which show how many gallons per cubic yard per 24 hours of your tank liquor or tank liquors could be satisfactorily purified on a percolating filter, and how many gallons per cubic yard on contact beds? If so, would you kindly state the results, at the same time telling us in precise terms what was the composition of your tank liquor or tank liquors, and what you are considering to be a satisfactory effluent?—In actual practice we treated on our contact beds 170 gallons per cubic yard on each bed, or 85 gallons per cubic yard on the combined beds. On the percolating bed 100 gallons per cubic yard were treated. The result was a much better effluent from the percolating bed than from the contact bed. The following is the average analyses on the two systems :—

	Contact System.		Percolating System.		
	Tank.	2nd Contact.	Tank.	Bed Effluent.	Settled Effluent (two hours).
Oxygen absorbed (4 hours' test)	5·25	1·08	5·54	1·22	0·83
Ammoniacal nitrogen	1·36	·49	3·40	·51	·51
Albuminoid nitrogen	·38	·10	·78	·12	·10
Nitric nitrogen	nil	·66	nil	1·46	1·40
Chlorine	7·7	7·6	8·3	8·1	8·1
Solids in suspension	—	—	9	5	1·5

I consider the settled effluent to be of a fairly good type.

21194. Could you express an opinion as to how the number of gallons would vary with variations in the strength of your tank liquor, and on what figure or figures you would rely for defining the "strength" of your tank liquor?—No. I don't think it practical to decrease the volume according to strength. In our works we get the largest dry weather flow when the sewage is strongest, *i.e.*, between 10 a.m. and 5 p.m. The beds have to be worked in the same ratio as the flow, with a corresponding decrease in the quality of the effluent.

21195. Have you had experience of storm water filters? If so, would you kindly give us the results of it?—We have storm filters in operation at both our works. I find the action of the storm filters is more mechanical than chemical. The sewage passes through at such a rate that there is no time for bacterial action. The action is merely a retention of part of the suspended solids on the material.

21196. Do you consider storm water filters lose any of their efficiency by being used intermittently at long intervals?—In the method of working, storm filters do not acquire the efficiency of either contact beds or percolating filters. The efficiency of our beds, which is one straining, is not affected by long intervals of rest.

21197. Have you any practical suggestions to make for disposing of sludges?—The screening refuse is very offensive and should be burned in a destructor ; the material from detritus tanks soon loses its offensiveness, and may be tipped on low-lying lands ; the sludge from precipitation tanks should be pressed, and either burned or used as manure ; and the sludge from septic tanks should be pressed and burned along with ashpit refuse.

21198. Do you find that some methods of disposing of sludge are more likely to cause nuisance than others?—There is very little nuisance caused by burning sludge. In using sludge as manure there is danger of farmers storing it near public roads and footpaths, and causing a nuisance in this manner. Very strong complaints were made to us during last summer, and orders were issued forbidding farmers to stack the sludge near public roads.

21199. What, in your opinion, constitutes a good effluent?—In my opinion a good effluent is one (a) which will not absorb more than ·7 parts of oxygen from $KMnO_4$ in four hours ; (b) which does not contain more than ·07 parts of albuminoid nitrogen ; (c) which will not undergo secondary decomposition when incubated at 80° F. for five days ; (d) which will not destroy more than its own volume of aerated tap water when incubated at 80° F. for 48 hours ; (e) which contains an abundance of nitric nitrogen.

21200. Do you consider that the type of effluent form a contact bed is superior or inferior to the type of effluent from a percolating filter?—I consider an effluent from a percolating filter to be of a better type than an effluent from a contact bed. In a percolating bed effluent the general impurities I find less, the effluent better aerated and better nitrated. The suspended solids settle more readily, and the effluent is less liable to undergo secondary decomposition.

21201. What test or tests do you chiefly rely upon in judging of the quality of an effluent, and for what reasons?—The tests I chiefly rely on are the oxygen absorbed figures from $KMnO_4$, 3 minutes and 4 hours, and the albuminoid nitrogen. These tests are the tests acknowledged by the Mersey and Irwell Joint Committee, under whose jurisdiction our works are. Apart from this I consider the tests to give the best idea as to the purity of an effluent. The oxygen test is one which any intelligent manager could make, and thus be enabled to know the condition of the works. The secondary decomposition and aeration tests I consider very valuable.

21202. Have you tried the "aeration" test, *i.e.*, the rate at which dissolved oxygen is taken up by an effluent?—Yes ; though not systematically, until Mr.

Scudder brought out his modification of the indigo method.

21203. Is one standard for all effluents passing into non-potable streams possible and desirable, or should there be more than one standard?—I think a general standard ought to be aimed at, which, whilst not overburdening the authorities, would safeguard our rivers. Different standards for different authorities I am afraid would not be favourably received by those authorities who unfortunately had to conform to the higher standard. The following modified Mersey and Irwell Joint Committee standard I consider liberal, and could be obtained by a good proportion with ease:—Oxygen absorbed from $KMnO_4$ in 4 hours, 1·50; albuminoid nitrogen, ·12; to be non-putrescible when incubated for 5 days at 80° F.; not to destroy more than two volumes of aerated tap water when incubated at 80° F. for 48 hours; should have nitric nitrogen present, and organic solids in suspension should not exceed 1·5; all in parts per 100,000.

21204. What is your experience of the effect of storm water upon filters of various sorts?—My experience is that storm water has a very serious effect on the upper layers of contact beds. When large quantities of storm water are turned on contact beds, the upper layers rapidly become choked. The same action takes place on storm filters; the solid matter accumulates on the surface of the beds, and has to be removed periodically. If the storm water was settled in a tank previously to going on the filters, a great deal of this trouble would be obviated.

21205. How far do you consider it advisable for a sewage installation to be worked automatically?—In percolating installations working intermittently I consider an automatic apparatus an essential feature. The apparatus should act over a great variation of flow, say from 1 to 12, so as to enable it to deal satisfactorily with the minimum night flow and the maximum day flow. It should be so arranged that it will deliver the low night flow on to one bed for any desired length of time, and at the end of this period it should automatically divert the flow to the next bed. Should the flow increase through rain or any other cause, the apparatus should bring additional beds into operation in ratio to the flow until there are sufficient at work to deal with the maximum flow, in this manner preventing excessive flows being turned on the beds. As the flow decreases the beds should be automatically put out of action in the same ratio as the flow, the cycle of changing being constant, so that all the beds get equal shares of liquid. The apparatus should have a simple arrangement to allow any bed being put out of action for a prolonged rest should necessity arise, though should excessive flow occur and the full resources of the works be required, this bed should automatically come into action during the time of pressure. These are the conditions which a satisfactory distribution should fulfil. I have designed a distributor, which is at work at Heywood, which conforms to all the conditions. With any distributor which will fulfil all these conditions, I think the feeding of the beds may be done automatically with advantage.

21206. Have you made any systematic observations as to the effects of discharging effluents into watercourses? No.

21207. Could you make a short statement setting forth the values you attach to the different chemical tests in use for determining the qualities or conditions of sewages and effluents, and giving your reasons?—I attach most value to the oxygen absorbed test from $KMnO_4$. Although it does not always bear a strict ratio to the other impurities, yet I always find with a low oxygen absorbed figure that the other impurities are not great. The secondary decomposition I do not find taking place with a low oxygen figure, and the rate at which dissolved oxygen is taken up is low. The chlorine test is always valuable to ascertain whether the sample of effluent is representative of the preceding sample of sewage. The value I attach to the nitrites and nitrates is in ascertaining the condition of the bed. The albuminoid nitrogen I consider gives a good clue to the putrescible matter in the effluent. The rate at which dissolved oxygen is taken up is, I consider, of great importance, as it gives us a good clue as to the effect the effluent will have on the river. The secondary decomposition test is an important one, as it gives a good idea as to whether the effluent is liable to cause a nuisance through developing offensive odours.

21208. What are your views with regard to the quantitative determination of the "strength" of a sewage, tank liquor, etc.?—The following is my idea as to the strength of sewage and tank liquors (parts per 100,000):—

Oxygen absorbed (4 hours' test).	Albuminoid Nitrogen.	——
9 and above	·9 and above	Strong sewage
5 to 9	·5 to ·9	Fairly strong
5 and under	·4 and under	Weak
5 and above	·4 and above	Strong tank liquor
3 to 5	·2 to ·4	Fairly strong
Under 3	Under ·2	Weak tank liquor

21209. On Question 21095, would you tell me on what river you derive your experience which leads you to say that "on a river of thirty times the volume of the inflowing sewage effluent the river becomes seriously polluted during the first rushes of storm water"?—At Heywood, on the River Roach, which flows past our works.

21210. On Question 21122, have you had actual experience that it is possible by too slow working of septic tanks to get the effluent giving off very offensive odours of sulphuretted hydrogen?—Yes. We have in our present works as an experiment a septic tank in slow working and in that tank we invariably get a very offensive odour of sulphuretted hydrogen given off.

21211. You have evidence yourself that that is owing to the fact that the working of it is too slow?—Yes; I could not account for it by any other cause.

21212. In Question 21135, you say that a very offensive smell is given off from the septic tank?—Yes.

21213. Does that come from the tank itself or from the liquid as it passes out of the tank on to the filter?—More particularly from the liquid.

21214. Is it constant or is it only when the tank is working too slow?—One has really to take other people's views on that, because you get so accustomed to being continually on the works that you do not notice any slight odour arising, but people coming down to the works very often complain of the offensive odour.

21215. Many witnesses say that there is no nuisance at all; I do not know whether yours is exceptional?—That is not my experience. My experience is that the odour is offensive.

21216. (*Mr. Power.*) Are your beds fed with a sprinkler?—No, by open troughs.

21217. (*Chairman.*) As regards the question of expense, have you any figures to support your conclusions as stated in Question 21138?—No. The first expression is purely an opinion. We conducted a small experiment by means of a centrifugal tank with baffle plates fixed at the sides, so that as the sewage went over, the solid matter was thrown out by centrifugal action and deposited between the plates. The head that we lost was so great that we could not adopt the system at our works.

21218. On Question 21141, have you had any experience of the soil working up into the filtering material?—Yes. The first filter that we put down was on a clay

Mr. Joshua Bolton.

10 May 1905.

bed, and the clay worked up and made an impervious mass around the drain pipe, so that we had to discard that and put in a concrete bottom. That experiment was carried out with a view to constructing our storm filters with clay bottoms, but we came to the conclusion after that small experiment that it would be a failure. Consequently we concreted the whole area of 6,200 square yards of the storm beds.

21219. In Question 21165 you say that the cost of your single contact beds works out at £21,240 per acre?—Yes.

21220. That is an enormous sum, is it not?—Yes, that is an enormous sum, but our filters are constructed very elaborately, with massive copings, blue bricks, very powerful walls, glazed brick outlet channels, and polished stone approach steps. They are very expensive indeed.

21221. Do you believe them to be worth the money?—They are worth the money, but the money is not necessarily spent. The value is there, but it is to no purpose.

21222. (*Mr. Power.*) I wish to ask one or two questions especially about the storm waters. In Question 21066 you say that your average dry weather flow is between 600,000 and 700,000 gallons per 24 hours?—Yes.

21223. In Question 21070 you tell us that there are no storm overflows fixed on your sewers; that the whole of the storm water is conveyed to the entrance to the sewage works where there is a primary screen, and that the grosser solids are arrested before the storm water passes over the storm overflows to the river. This takes place when you get down six times the dry weather flow, namely, 4,200,000 gallons?—Yes.

21224. Then in Question 21073, speaking of heavy rains, you say "gaugings during very heavy rain have registered at the rate of 30,000,000 gallons per 24 hours." Therefore during part of the day you may have storm water sewage coming down at the rate of 30 times the dry weather flow?—That is so.

21225. That goes directly into the river?—That goes directly into the river after the grosser solids have been removed by the screens.

21226. What is the ratio of your effluent to the river in ordinary times?—One in 30.

21227. And does this storm sewage come down to you before the river is in flood?—Oh, certainly.

21228. Is it a grossly polluting liquid?—Yes, it is grossly polluting, and the first rushes of storm water have a detrimental effect on the river.

21229. Have you considered any method by which that could be dealt with or controlled—or any part of it? I notice that later on you say that twice the dry weather flow is sufficient to deal with by the whole of your process, and you think that the balance—which would be four times or more the fine weather flow—should be dealt with by settlement tanks and then passed on to the percolating filter or straining filter—which was it?—The percolating filter.

21230. That is a deep filter?—Yes.

21231. At what rate?—We propose about 500 gallons a square yard per day of 24 hours. That would work out somewhere about 200 per cubic yard.

21232. Do you think it would be feasible in a case like yours where there are no overflows on the sewer to subject some of the liquid beyond the six times the dry weather flow to settlement, so as to prevent the pollution of the river?—Yes, I think it is quite feasible and that it is far more satisfactory than turning it on to the storm filters as we do at present. In fact, we might increase the flow through the tank and arrest the grosser solids.

21233. As a matter of fact, it is not negligible, because in the course of the year you estimate that 139,000,000 gallons passed to the river in that way?—Yes.

21234. Do you think it would be costly in the sense of greatly increasing the amount of settlement tanks?—It would be very costly in increasing the settlement tanks in proportion to the increased number of volumes we tried to treat.

21235. Are the 30,000,000 per 24 hours in any given day? I suppose that is not maintained? It is a matter of minutes rather than of hours, is it not?—No; we have had that occurring for a full three hours.

21236. What is the greatest amount that has come down to you in one day and been passed through your works to the river? How much in any one day—not 30,000,000 gallons, or anything like it, I suppose?—No.

21237. There would be that 4,200,000 which you have dealt with?—Yes.

21238. In addition, in any given day, how much do you think has passed away to the river?—That is a question I could not answer without calculating the rainfall in our drainage area on any particular day. That would give us what had come down the main sewer in that day.

21239. Do you think it would be at least as much as the 4,000,000 you deal with?—Decidedly more; I should say double the quantity on some very wet days.

21240. How much should you think of this liquid coming at the rate of 30,000,000 gallons in 24 hours is a highly polluting liquid and should be dealt with?—That varies according to circumstances. In Heywood the first one and a half hours—that is the big rush—is undoubtedly very, very foul.

21241. Would it be so much as 12,000,000 gallons, do you think?—No. With 1 in. rainfall it would be 8,409,000 gallons.

21242. You would deal with twice the dry weather flow by the whole plant?—Yes.

21243. And the balance above that has to pass through settlement tanks?—Yes.

21244. And then through percolating filters?—Yes, through percolating filters.

21245. Anyhow, you could pass the balance through a settlement tank and later through a rough filter, I suppose?—Yes, we could do that comfortably. We would get rid of the first one and a half hour's flow—the heavy flow—and then we could give it an hour's settlement, which would give a fairly satisfactory effluent.

21246. What brought about the abolition of overflows on the sewers themselves, or was absence of overflows in the scheme from the first?—It was the opposition of the Mersey and Irwell Joint Committee against having so many different outlets for their inspectors to inspect. It was ultimately decided that we should convey the whole of the storm water to one storm overflow. Of course, another point which is not much in favour of the prevention of pollution of rivers was that the sewers would get a swilling out. That is the pith of the subject.

21247. Then if I might go a little further, I see that you have had some experiments in septic tank filtration?—Yes.

21248. Does your preference for dealing by the whole plant with only two volumes of the dry weather flow extend to the septic tank process?—Yes, more particularly.

21249. If you had a septic tank process instead of your precipitation process, you would prefer to deal with it on exactly the same lines as you propose to deal with the chemical process?—Yes.

21250. (*Major-General Carey.*) About this failure to deal with three times the dry weather flow mentioned in Question 21090. Does the fault not lie in the want of sufficient precipitation?—No.

21251. What is the capacity of your precipitation tank?—710,000 gallons. The chief reason why our effluent is so polluted in times of storm is that the incoming sewage enters almost at the bottom of the tank. The current immediately meets the sludge and throws it up at the other end—that is, the previously settled sludge. Our sewage is not passed in at the top of a tank and gradually run over the surface; it is passed in at the bottom of the tank. This method is perfectly satisfactory in normal times, but immediately a storm comes with an increased flow the velocity is so great at the bottom that the sludge is disturbed and thrown over the outlet.

21252. (*Mr. Power.*) In other words, your tank is filled with suspended matter by the storm water coming into it?—Yes, after the first hour.

21253. Would it be double as much suspended matter?—Sometimes quite double. In fact, we have decided to dispense with that method now—that is, with the method of feeding at the bottom of the tank.

21254. (*Major-General Carey.*) And deliver it at the top?—No, 3ft. from the top.

21255. That will remedy the disturbance of the sludge to some extent?—Yes, to a certain extent it will.

21256. Now about your storm beds. What is the total area of your storm beds?—The total area at the main works is 6,200 square yards, and at the Heap Bridge works, a small works in one of the out districts, 480 square yards.

21257. Is the storm water delivered over the whole or that surface?—It is not; it is delivered by a main trough down the centre.

21258. Does the whole of the area come into play?—No, it does not.

21259. Would not that account in a great measure for a part of it coming up if you simply use part of it?—Yes, we only use a part of it on the immediate side of the trough. Assuming we have here the storm bed with a trough running along down the centre, the flow goes over the trough and flows down at a very rapid rate in the path of the least resistance, which, when the bed is new, is immediately on either side of the trough. That gradually becomes clogged, and the water flows over the top.

21260. That is defective distribution?—Yes, that is purely a storm bed.

21261. If your distribution was better, and you used the whole of the area of the storm filters at your disposal, you would not have any trouble?—We should not have the same trouble, but still we should practically get the same trouble later through having the sludge distributed evenly over the bed in a thin, gradually increasing layer rather than in a large quantity near the trough.

21262. Do you distribute over the whole of that 6,000 yards?—I think so. We have on our storm beds two sprinklers of 60ft. diameter, which are my own patent. I put them down for an experiment there. We get into the sprinkler the storm water, and the whole surface of the bed has become choked in both sprinklers; in three months' time, delivering a maximum of 400 gallons per square yard per wet day, we find the bed is totally clogged.

21263. That only occurs at intervals?—No; the rate that I give you is calculated on six months' working.

21264. (*Mr. Power.*) What is the size of the material?—It is a 1in. mesh at the bottom; the material has been rejected by a 1in. mesh, but the upper 18in. has passed the 1in. mesh and been rejected by the $\frac{3}{4}$in. mesh.

21265. As a matter of practice, do you deal with the bed by forking the surface over continually?—No. I would rather wait until it dried and skim it cleanly off. It dries rapidly on the top, and the men can skim it off entirely.

21266. But the suspended matter involves the filter for some depth from the surface, does it not?—No, not more than two or three inches.

21267. (*Major-General Carey.*) On Question 21126: Would the nuisance caused by drawing off the sludge be removed or abated by emptying the tanks more frequently? You say, "A very offensive smell is given off, which would no doubt be a nuisance if dwellings were near." That is in emptying your septic tanks?—Yes, and the chemical precipitation tanks.

21268. Would that nuisance be removed or abated if you emptied the tanks more frequently?—No.

21269. I am speaking of the septic tank?—Yes, but we get the same odour from both tanks, but more particularly from the septic tank. A strong odour, however, is produced by the chemical precipitation tank.

21270. On Question 21152 will you kindly explain how one and a half times the volume put on the first contact bed can be treated on the second contact bed?—Assuming that the area of the first contact bed be 100, then the second contact bed would go down approximately to about 66.

21271. But you say about one and a half times the quantity of the first contact bed?—Yes, one and a half times the volume. That is, supposing we get 200 gallons through the first contact bed, then we can get on our area 300 per yard satisfactorily treated on the second contact beds. You diminish the second contact beds proportionately in area as $1\frac{1}{2}$ is to 1.

21272. But you cannot get more on the second contact bed than goes through the first?—Yes, we can get more through by diminishing the area.

21273. By diminishing the area, otherwise the charge must be the same?—Provided one delivered directly on to the other; but if it delivers into a channel from which the diminished area is filled, then we could get an increased volume per cubic yard through the second contact bed.

21274. In reply to Question 21158*, you say that 170 gallons per cubic yard can be treated on the first contact bed, or 85 gallons per cubic yard on the combined beds?—Yes. That just comes back to the previous question. During the time of the experiments we had two beds exactly the same size, the first contact bed and the second bed; we were compelled always to turn direct from the first contact bed on to the second contact, as we had not a channel between where we could turn it and increase the flow on a given bed. This is an actual experience with equal volumes on each bed. After that I tried some short experiments with feeding the second contact beds at more rapid intervals, and I found out that we could get one and a half times the volume through.

21275. (*Mr. Power.*) By giving it less contact?—By giving it less contact and a slightly less period of rest.

21276. (*Major-General Carey.*) The volume treated on the combined beds at both first and second contact is one and a half times the volume treated on the first contact?—No. You treat your 170 gallons per cubic yard; then in the combined beds you get double the area, and consequently you reduce the volume. Double area, half volume.

21277. (*Mr. Stafford.*) In your answer to Question 21140 you compare the cost of the three methods—quiescent settlement method, continuous flow settlement, and septic tank treatment—and apparently the septic tank treatment is the cheapest?—Yes.

21278. And the least efficient of the three?—No, they are of about equal efficiency. These are worked out on equal efficiency.

21279. But I see that the percentage of purification was 62 in one case, while in the case of the tank effluent it was only 36?—That is so.

21280. Thirty-six?—That is so; and then I have calculated the extra interest on the set of contact beds to bring them up to one standard, as we had to do. My actual experience is that chemical precipitation and one contact is about equal to septic tank and double contact; that has been my experience at Heywood.

21280*. Where do you bring it in?—In the interest and sinking fund on capital expenditure.

21281. £1,533 5s.?—Yes. I have accounted for that in the question because we should require a larger area of beds, and therefore I have worked out the cost of the increased interest and sinking fund in the same ratio.

21282. (*Colonel Harding.*) Returning for a moment to one of the points raised by Mr. Power and General Carey, viz., the storm waters: I suppose you have no doubt as to your figures of having at times brought to your works 40 times the dry weather flow?—Not the slightest.

21283. One is surprised to find that your sewer mains should be capable of bringing to the works such an enormous quantity?—Oh, they could deliver double that quantity.

21284. Does it not involve that the flow during normal times is exceptionally slow?—Fairly slow, but with an egg-shaped culvert.

21285. That corrects the flow to a certain extent. Is it a flat or a hilly country?—It is fairly hilly. Our main outfall sewer is a brick culvert 3ft. 6in. by 2ft. 6in., which will easily deliver that volume.

21286. You have told us what we have been told by others before, that in storm times the amount of suspended matter in the sewage is greatly increased?—Very greatly.

21287. And you have given us the result of an interesting experiment taken every hour during a storm, from which it appears that during the first rush you had up to 238 parts per 100,000 of suspended matter, and after several hours it had fallen to 18?—Yes.

Mr. Joshua Bolton.

10 May 1905.

21288. One gathers, therefore, that the impurities of storm waters consist mainly of suspended matter?—Decidedly so.

21289. In Question 21089 you tell us, nevertheless, that the liquid part of the sewage during storm times during the first two hours is very foul, do you not?—Yes. It is a foul liquid, but I am speaking there purely in comparison with the effluent. I am speaking of it as it goes to the river, not as sewage.

21290. I see. It is foul relatively to the excellence of the effluent which you ordinarily turn into the river, but not necessarily foul as compared with the ordinary dry weather sewage?—No; you have the correct interpretation there.

21291. Am I right in understanding that what you mean is that the impurities in storm water are mainly in the form of suspended matter, and that when the suspended matter has been removed you really relatively have a dilute liquid which is not foul?—That is so.

21292. The example which you give just before in Question 21089 shows that after you have removed the suspended matter the liquid which is not so good, no doubt, as your ordinary effluent is greatly better than your ordinary sewage?—Decidedly so.

21293. Does it not appear that the main business in connection with storm water is the removal of suspended matter?—That, in my opinion, would be the most satisfactory method of dealing with storm water—to give it an hour's settlement and get out the suspended matter.

21294. You do not advise that being done through the ordinary tanks, either the chemical precipitation or the septic tanks? You think there should be a special series of tanks?—A special tank, yes.

21295. So as not to disturb the normal condition?—That is so.

21296. The plan of storm filters which you have actually worked consisted in turning this unprecipitated storm water upon the storm bed?—Yes.

21297. And you find that the action of the storm bed is unsatisfactory because the action is rather mechanical than chemical?—That is so.

21298. It is, in fact, a strainer?—Pure and simple.

21299. And not a very efficient strainer, probably?—No.

21300. And it is difficult, after the straining, to remove the matters strained off?—The sludge that accumulates on the surface, yes.

21301. You would prefer settlement in tanks?—Yes.

21302. Having settled storm water, further treatment would not be difficult, if required, would it, upon percolating beds?—I do not think so.

21303. You have percolating beds, have you not?—We have only two sprinklers, but part of the storm filters works as a percolating bed.

21304. But you have not experimented in putting settled storm water on the percolating beds?—No.

21305. You have expressed the opinion that probably double the flow might be treated as settled water?—Yes. In fact, at present we are getting out quantities for constructing 12 60-ft. diameter percolating beds, and that is our object—to increase the flow in times of storm.

21306. Do you believe it would be easier to deal with a large flow of settled storm water on percolating beds than it would be upon contact beds?—I do.

21307. In Question 21106 you express the opinion that it would be easier to filter chemically precipitated sewage than septic tank effluent. Is that not because the chemically precipitated sewage is much freer from suspended matter?—Yes.

21308. Are you able to give us an opinion, based upon your own experience, as to whether you think it would be easier to deal with chemically precipitated effluent than septic tank effluent, provided suspended matter in both cases was the same?—I could not vouch an opinion upon that, because it is a most difficult matter to reduce the suspended matter in the septic tank effluent down to the same figure as the suspended matter in the chemically precipitated effluent. It would mean some mechanical filtration—some further settlement or mechanical sieving would be necessary to reduce the suspended matter.

21309. What you mean is that, not having had experience of effluent cleared of suspended matter, you are unable to answer the question?—That is so.

21310. (*Mr. Power.*) I suppose, in regard to the facts you speak of here, the precipitation tanks were never used to deal with more than twice the volume of the dry-weather flow?—They are very satisfactory so long as you do not deal with more than twice the dry-weather flow?—That is so. Directly you get above that you begin to disturb the sludge at the bottom, or get such a rapid flow that you have not time for an efficient settlement.

21311. Then the result would come nearer that with the septic tank?—In that case, so far as regards suspended solids, yes.

31312. (*Colonel Harding.*) You have told us of the difficulty which you find in reducing the suspended matter in septic effluent to the low point which you desire?—Yes.

21313. It would be very important if the septic effluent could be obtained with much less suspended matter?—Yes.

21314. You have not any idea of how it could be obtained, have you? Have you tried any experiments?—We tried a circular tank with baffle plates, but the head we lost was so great.

21315. You told us that. But that did not succeed. Have you heard of any other way by which it might possibly be done?—Yes, I have heard of mechanical filtration by means of passing it through felt. The experiment was carried on in the neighbourhood close to us, at Ratcliffe. It was a mechanical filter whereby the liquid was passed on to a long felt band and filtered through the felt. The felt was gradually moving, and brushes were brought into action later on to clean off the sediment which had been collected on the band. The band was then passed under revolving rollers and presented again to the sewage.

21316. Probably it was found that a very thin volume of sediment would cause the felt to be quite impervious?—That is so, but the felt was always moving and always being cleaned.

21317. But was it successful at all?—The expense was too great. It was discarded.

21318. It was prohibitive?—Yes, and it was discarded entirely.

21319. You have not found that passing the septic effluent through a second settling tank gets rid of any part of the suspended matter?—I have not had an opportunity of testing that.

21320. (*Mr. Power.*) Is your septic plant on a small scale?—Yes, but there is one at work now with a capacity of 110,000 gallons.

21321. How long has that been in operation?—That has been in operation since February 22.

21322. So that you have had no great experience of it yet?—Yes. I have some analyses, but they are not in the state I should like them to be in yet. I have not sufficient figures to vouch any special opinion, but I could tell roughly the percentage of purification on the oxygen test. We are improving very considerably on what we did on the small one. Our percentage of purification on the large tank, based on the oxygen-absorbed test, is 55.

21323. The greatest flow during rain would be what?—Not more than double the dry-weather flow. We limited it to that. Do you mean the average dry weather flow?

21324. Not the average; the quickest rate would be one in 12 hours?—Yes.

21325. (*Colonel Harding.*) What is the amount of suspended matter in the sewage when going into the tank in that experiment?—It is the same as in the chemical precipitation, which runs at about 38 or 39.

21326. What is the amount of suspended matter coming out in the septic tank effluent?—We do not get very satisfactory results there; we get often eight or nine parts, particularly now. It appears to be going worse now. The sludge is rising from the bottom and is thrown over the outlet sill until we get seven, eight, or nine parts.

21327. (*Mr. Power.*) You have not had much sludge since February, have you, in a septic tank of that size?—A fairly large amount; it is beginning to rise considerably now.

21328. (*Mr. Power.*) That is rather rapid production of sludge, is it not?——

21329. (*Colonel Harding.*) Yes; one would scarcely expect it to be very full at present?—(*Witness.*) When I speak of the rising of the sludge I do not refer to rising in depth; I mean the gases are now beginning——

21330. (*Colonel Harding.*) You mean the septic action is developing?—The septic action has disturbed it, yes.

21331. I thought the sludge was accumulating?—No, that would be rapid.

21332. Do you find the amount of suspended matter in the effluent is also increasing?—That also is increasing.

21333. Naturally, as the tank accumulates sludge that will continue to increase?—That is so.

21334. Until it reaches a prohibitive point, and then you will clear out the tank?—Yes.

21335. That leads me to ask you whether it would not be very valuable if you could maintain a constant capacity in the septic tank by not waiting until the tank is practically full of sludge, but by emptying some sludge daily or weekly so as to maintain a constant capacity?—That would be perfectly satisfactory, in my opinion, if the works were designed with that object in view.

21336. Is it practicable, do you think, to construct tanks to attain that object?—Yes, simply by constructing an extra tank so that you could give a tank a rest.

21337. If it is possible, do you think it desirable?—Yes.

21338. So as to maintain a constant capacity?—Yes.

21339 To prevent the increase of suspended matter in the effluent from the septic tank?—Yes. My evidence was based purely on the conditions under which I have to work.

21340. You have said something about the scum on the septic tank being in your opinion of no practical value unless it be in keeping in the smell?—Yes.

21341. How can the scum do that?—Will you refer me to the question.

21342. It is in answer to Question 21117. You say, "A scum has the advantage of keeping the smell down." Would you mind telling us how?—That was very noticeable in our small tank when we had a scum on. In calm weather the smell was not so noticeable as it was when the wind had disturbed the scum and cleared it off the tank.

21343. But the fact of there being a scum there does not prevent the evolution of gases?—No.

21344. The scum is not impervious; it does not confine the gases?—No. But in windy weather when there is no scum, there is a gradual current of the upper layer of water. As the wind drives this water along the surface of the tank, it is replaced by water from a lower depth, and thus we get more water exposed, and consequently a more offensive odour given off.

21345. You express a similar opinion with regard to covered septic tanks; that a covering might be useful in cases where it was important to keep down the smell. There again, how does the cover of the septic tank prevent the escape of gases. They cannot be for ever confined and accumulated under the cover of the septic tank, can they?—No, but if there was any offensive odour given off you must have the gases confined and conveyed to some method of destruction.

21346. The utility of the cover would be to enable you to carry away the gases—possibly to burn them?—Yes, that is so.

21347. Or to make them innocuous in some way?—Yes, that was my point. In that case you would have control of the offensive gases.

21348. Do not the gases consist mainly of methane, and hydrogen, and so on?—But in the long working of a tank we get a decidedly offensive odour.

21349. Is not that due to the movement of the septic tank effluent?—No, as the tanks work too slowly we get a black effluent and an offensive odour.

21350. By over septicising there is a production of hydrogen or other evil-smelling gases?—Yes.

21351. In reply to Question 21126 you make an interesting suggestion about the burning of the pressed sludge from septic tanks. Have you any experience of that process at all?—Yes, we have tried it at our small tanks. We took the sludge up to the destructor, which is in close proximity to the works, where it was burnt along with the ashpit refuse. We got no offensive odour at all from it.

21352. Would it be expensive to burn the cake from the septic tanks sludge?—I do not think the expense would be great apart from the carting of the sludge to the destructor.

21353. There would be a considerable amount of moisture in it?—Yes.

21354. You are of opinion from the small experiment you made that the burning of septic tank cake would be practicable, and that it would not be offensive?—I think that would be the best means of disposing of sludge—by burning.

21355. In reply to Question 21142 you expressed the opinion that a contact bed ought not to be deeper than 4ft. Upon what do you base that opinion?—By inserting tubes in the filter and withdrawing portions of the effluent and testing it, we find that the purification oxidation is more rapid in the upper layers.

21356. That is a point of considerable interest. You have tried a bed much deeper than 4ft., and at different points you put in tubes which enabled you to test the part below 4ft., but below 4ft. you got no practical improvement?—We do not get the same purification in any way to the same degree lower down. In fact, in some experiments that I worked out we got at 6ft. in two hours an equal purification to that which we got in a quarter of an hour in the first foot of the bed—that is, at a depth of 6ft. in two hours you get the same oxidation as you get in a quarter of an hour in the first foot of the bed.

21357. Let us quite understand what you mean. What was the depth of the experimental bed?—6ft.

21358. And at each foot had you a tube which you could withdraw?—Tubes with corks at the top.

21359. How did you extract the liquid?—It rises in the tube.

21360. And you found that the percentage of oxidation in the first foot was greater than in the last?—Yes.

21361. One can appreciate that, but did you not find an improvement in purification as you went to greater depths? In other words, would the results of purication on a bed 4ft. deep be better or worse than the purification on a bed 6ft. deep?—I think that would depend entirely on the method of feeding. When you do down in a rapid stream as we do down the side of the bed by a trough you do not get the same proportion. I found, according to some figures which I give later, that the first rushes coming down the bed washed out the nitrates; we get a well-nitrated effluent, but by continually running through we do not get the same amount of purification.

21362. Your uneven distribution to a certain extent vitiated the experiment?—That is so.

21363. Do you think that with reasonably good distribution upon a contact bed 6ft. deep the greater part of the bed would be acting during filling as a percolating bed?—That is so.

21364. And likewise during the process of emptying it would be acting as a percolating bed, and its greater depth would give it a great advantage in regard to those periods of the process?—My opinion is that with proper distribution you would get an advantage by deeper bed.

21365. We are not to take it that your opinion is that there is no advantage in carrying a contact bed to a greater depth than 4ft.?—There is no advantage. But I form that opinion on the method of distribution that we have. We get the effluent run down in a trough.

21366. Then we are to modify the opinion that you expressed to that extent—that in your special circumstances it is no use having a greater depth than 4ft., but you think that in other conditions there probably would be an advantage in deepening the bed?—But it would then be more on the lines of a percolating bed.

21367. Then, passing on to the percolating bed, you have told us that if it is put on the percolating bed

Mr. Joshua Bolton.

10 May 1905.

it necessarily involves that suspended matter will come out in the filtrate from the bed, and that if the flow be at times considerably increased the discharge of suspended matter will also be considerably increased, and, that at those times it comes out, I think you say, in the form of humus?—Yes.

21368. I suppose in normal times the suspended matter in the filtrate is brown—earthy?—Yes.

21369. But if the discharge is at a much greater rate of flow than usual it would be scarcely humus, but probably black and unoxydised?—That is so, and far larger quantities. By holding the sprinklers in one position we can bring about the same action.

21370. You have reached the conclusion that such accumulations as take place in a sufficiently coarse percolating bed may be washed out by an increased flow?—Yes.

21371. In any case, unless you have thoroughly clarified sewage on the percolating bed you must have suspended matter in the flow?—That is so.

21372. What process do you suggest as the best to follow percolating filtration in those conditions?—I think the large settling tank in all cases ought to follow the percolating bed.

21373. Have you tried the process of settlement following percolation?—Yes.

21374. What results have you obtained? How low were you able to bring down the suspended matter in filtrates afterwards settled?—We could easily get down to one, and generally in four hours it is practically free from suspended matter. There is no appreciable suspended matter after four hours' settlement.

21375. You think that with percolating filters which receive suspended matter there must be a further process?—Decidedly so.

21376. And the further process which you suggest as efficient is settling?—Yes, a settling tank.

21377. There occurs to me a rather interesting point. If you are obliged to have subsequent settlement following percolation, it does not very much matter how much suspended matter you bring to the filter, does it? You might have imperfectly settled sewage, if it was going through the filter and was afterwards to be settled?—My opinion is that the suspended matter in unoxydised effluent is more gelatinous in form, and does not settle nearly so rapidly as the humus matter which comes away from the percolating bed.

21378. I quite appreciate that. That is an advantage of subsequent settlement; but suppose you put crude sewage upon a percolating filter which was sufficiently coarse, you would get a large quantity of suspended matter coming out in the filtrate?—Yes.

21379. Would the suspended matter which you had then be better settled following filtration than preceding filtration? I think you said that the matter coming out after filtration is to a large extent oxidised, that it is granular, and that it settles rapidly. Would you think it likely that settlement following upon filtration might be substituted for settlement preceding filtration?—I do not think so; I think the product would be the same. We should still have the glutinous form of sludge if the bed was overworked.

21380. If the bed was overworked?—Yes.

21381. But one is assuming that it is not overworked?—That would be tolerably slow.

21382. However, you have not had experience in that, and you are not prepared to express an opinion, as I gather?—That is so.

21383. But you have noticed that the suspended matter coming out of the percolating beds is more granular and more easily settled than the suspended matter in sewage?—That is so.

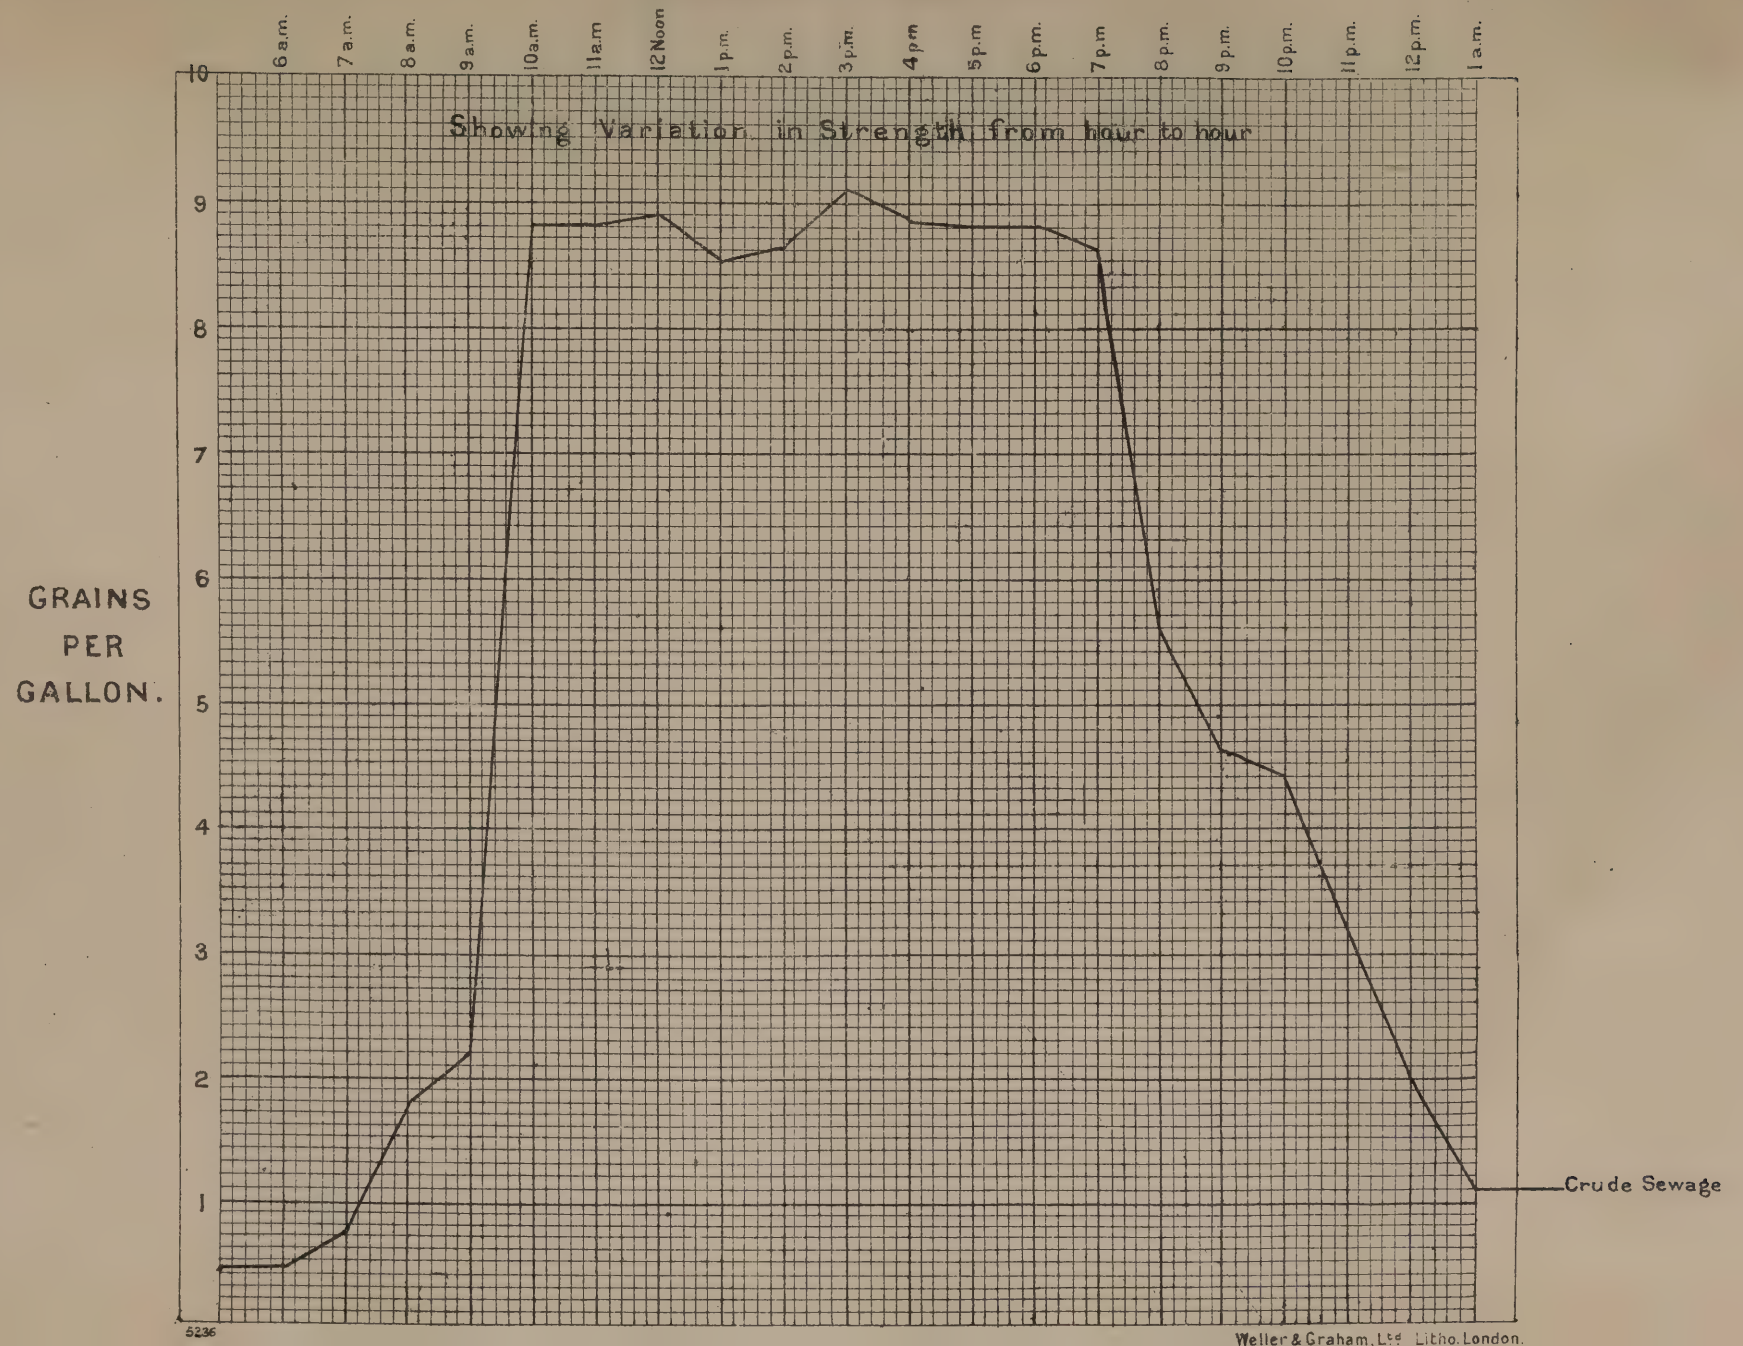
21384. In reply to Question 21189 you refer to vegetable fungoid growths on the surface of percolating filters. I am interested to see that you think that intermittence in the feed tends to prevent that?—Yes; that was very noticeable.

21385. In reply to Question 21190 you expressed the opinion that percolating filtration is more likely to give rise to a nuisance than contact?—Yes.

21386. Why so, assuming that in both cases the same effluent is put on?—Because if the liquid is offensive, if it contains offensive gases, there is far more chance of the gases being liberated when the flow is divided up into a small number of sprays than there is in rushing it over a weir.

21387. We understand that. Possibly the nuisance would arise not from the filtration, but from the spray which precedes?—Yes, that is so.

21388. From your answer to Question 21193 I gather that you think you could pass a larger volume per cubic yard through percolating beds than through contact beds, and also obtain better results?—Yes.



21389. You are assuming, of course, that the liquid treated will be the same? You do not mean that the results of your percolation have been better than the results of contact under different conditions, but with the same effluent from the septic tank or from chemical precipitation you think you can get more volume through a percolating filter per cubic yard than through a contact bed, and also get better results?—And also get better results, yes. That is shown in the analyses which I give.

HEYWOOD.

Appendix to Evidence of Mr. Joshua Bolton.

Tables showing average analyses of sewage, tank liquor, and filter effluents at Bolton, January, 1903—August, 1904.

PROCESS OF TREATMENT:

Chemical Precipitation and Single Contact Beds.

HEYWOOD. January, 1903.

SEWAGE—

Average daily flow	1,412,548 gallons	Month's rainfall	3·65 inches.
Maximum daily flow	2,930,625 „	Rainfall	·56 „
Minimum daily flow	645,373 „	Rainfall	nil.

Average Analysis of Sewage.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	2·63	3·78	3·17
Albuminoid Nitrogen	·68	·92	·80
Nitric Nitrogen	nil	nil	nil
Chlorine	5·90	6·8	5·9 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	6·20	8·26	7·17 „ „
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 4.

TANK LIQUOR—

Average daily flow through the Tanks	1,412,548 gallons = to 11 hours 3 minutes in tanks.
Average number of Tanks in use	5½.
Amount of Chemicals used during month	9 tons 19 cwts.
Amount of Sludge dealt with during month	1,495 tons 15 cwts.

Average Analysis of Tank Liquor.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	1·68	2·76	2 14
Albuminoid Nitrogen	·28	·35	·29
Nitric Nitrogen	trace	nil	—
Chlorine	5·8	6·8	5·2 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	1·78	3·60	2·45 „ „
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 4.

FILTERS.

Number of times Beds were filled during month	99.
Average duration of contact	1 hour 50 minutes.
Amount of Tank Liquor treated (gallons per cube yard per 24 hours)	185.

Average Analysis of Filter Effluent.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	2·26	3·62	2·91
Albuminoid Nitrogen	·10	·31	·21
Nitric Nitrogen	·42	·09	·23
Chlorine	5·6	6·5	5·5 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	·79	1·53	1·13 „ „
Dissolved Oxygen	·40	·14	·25
Suspended solids	—	—	—

Number of samples analysed for the average = 4.

REMARKS.—The samples of Filter Effluent have generally a slightly turbid appearance, but are free from smell and contain no suspended matter.

February 1st, 1903. *Joshua Bolton.*

HEYWOOD—*continued.*

February, 1903.

SEWAGE—

Average daily flow - - - 1,286,821 gallons - Month's rainfall - - - - 3·42 inches.

Maximum daily flow - - - 2,616,000 „ - Rainfall - - - - - - ·12 „ (Snow previous day)

Minimum daily flow - - - 694,500 „ - Rainfall - - - - - - nil.

Average Analysis of Sewage.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	2·08	3·60	2·58
Albuminoid Nitrogen	·52	·92	·72
Nitric Nitrogen	nil	nil	nil
Chlorine	6·8	7·32	6·9 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	4·82	8·72	7·15 „ 20
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average=4.

TANK LIQUOR—

Average daily flow through the Tanks - - - - - - - - 1,286,821 gallons=to 12 hours 8 minutes in tanks.

Average number of Tanks in use - - - - - - - - - $5\frac{1}{2}$.

Amount of Chemicals used during month - - - - - - - 9 tons 10 cwts.

Amount of Sludge dealt with during month - - - - - - 1,390 tons 12 cwts.

Average Analysis of Tank Liquor.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	1·71	3·10	2·29
Albuminoid Nitrogen	·38	·58	·45
Nitric Nitrogen	trace	nil	nil
Chlorine	6·8	7·2	6·7 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	1·90	3·40	2·40 „ 20
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average=4.

FILTERS—

Number of times Beds were filled during month - - - - - 84.

Average duration of contact - - - - - - - - - - 2 hours.

Amount of Tank Liquor treated (gallons per cube yard per 24 hours) - 174.

Average Analysis of Filter Affluent.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	2·14	2·86	2·37
Albuminoid Nitrogen	·14	·30	·19
Nitric Nitrogen	·71	·17	·44
Chlorine	6·8	7·6	6·6 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	·86	1·21	1·07 „ 20
Dissolved Oxygen	·46	·27	·36
Suspended solids	—	—	—

Number of samples analysed for the average=4.

REMARKS.—The samples this month have been generally clearer than last month, and have been quite free from smell.

Joshua Bolton.

March 1st, 1903.

HEYWOOD—*continued.*

March, 1903.

SEWAGE—

Average daily flow - - - 1,573,000 gallons - Month's rainfall - - - - 3·73 inches
Maximum daily flow - - - 3,407,250 „ - Rainfall - - - - - ·47 „
Minimun daily flow - - - 680,000 „ - Rainfall - - - - - ·01 „

Average Analysis of Sewage.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	2·93	4·11	3·81
Albuminoid Nitrogen	·63	1·47	1·07
Nitric Nitrogen	nil	nil	nil
Chlorine	5·0	6·5	6·5 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	3·0	9·71	5·88 „ 20
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 4.

TANK LIQUOR—

Average daily flow through the Tanks - - - - - - - 1,573,000 gallons = to 10 hours in Tanks.
Average number of Tanks in use - - - - - - - - 5½.
Amount of Chemicals used during month - - - - - - - 9 tons 10 cwts.
Amount of Sludge dealt with during month - - - - - - 1,495 tons 15 cwts.

Average Analysis of Tank Liquor.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	1·69	1·81	1·94
Albuminoid Nitrogen	·24	·38	·29
Nitric Nitrogen	trace	nil	—
Chlorine	6·2	6·7	6·4 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	1·78	2·86	1·98 „ 20
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 4.

FILTERS—

Number of times Beds were filled during month - - - - - 96.
Average duration of contact - - - - - - - - - 1 hour 55 minutes.
Amount of Tank Liquor treated (gallons per cube yard per 24 hours) - 178.

Average Analysis of Filter Effluent.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	·52	1·40	1·32
Albuminoid Nitrogen	·10	·14	·10
Nitric Nitrogen	·68	·31	·69
Chlorine	4·2	6·4	6·4 av. of 20
Oxygen absorbed from $KMnO_4$ in 4 hours	·40	1·30	·66 „ 20
Dissolved Oxygen	·65	·71	·49
Suspended solids	—	—	—

Number of samples analysed for the average = 4.

REMARKS.—The Filter Effluent has been on the whole fairly clear, and containing no suspended matter, and being free from smell.

Joshua Bolton.

April 1st, 1903.

HEYWOOD—*continued.*

April, 1903.

SEWAGE—

Average daily flow - - - 882,366 gallons - Month's rainfall - - - - 2·19 inches
Maximum daily flow - - 1,541,625 „ - Rainfall - - - - - ·15 „
Minimum daily flow (Sunday) - 511,875 „ - Rainfall - - - - - ·01 „

Average Analysis of Sewage.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	3·67	3·27	3·30 av. of 3
Albuminoid Nitrogen	·88	·74	·81 „ 3
Nitric Nitrogen	nil	nil	nil
Chlorine	7·8	9·0	8·3 av. of 18
Oxygen absorbed from $KMnO_4$ in 4 hours	8·42	9·71	6·25 „ 18
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

TANK LIQUOR—

Average daily flow through Tanks - - - - - - - - - 882,366 gallons = to 17 hours. 42 minutes in Tanks.
Average number of Tanks in use - - - - - - - - - $5\frac{1}{2}$.
Amount of Chemicals used during month - - - - - - - 10 tons 19 cwts. 3 qrs.
Amount of Sludge dealt with during month - - - - - - 1,405 tons 4 cwts.

Average Analysis of Tank Liquor.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	1·69	2·34	2·55 av. of 3
Albuminoid Nitrogen	·27	·53	·39 „ 3
Nitric Nitrogen	trace	nil	—
Chlorine	6·2	7·1	7·5 av. of 18
Oxygen absorbed from $KMnO_4$ in 4 hours	1·78	2·50	2·25 „ 18
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

FILTERS—

Number of times Beds were filled during month - - - - - 90.
Average duration of contact - - - - - - - 2 hours.
Amount of Tank Liquor treated (gallons per cube yard per 2 hours) - 168 gallons.

Average Analysis of Filter Effluent.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	1·20	1·81	1·76 av. of 4
Albuminoid Nitrogen	·10	·22	·14 „ 4
Nitric Nitrogen	·56	trace	·30 „ 4
Chlorine	7·8	7·0	7·4 „ 18
Oxygen absorbed from $KMnO_4$ in 4 hours	·44	1·32	·74 „ 18
Dissolved Oxygen	·42	·04	·21 „ 4
Suspended solids	—	—	—

REMARKS.—The Filter samples are almost clear, and contain only a very small quantity of suspended matter.

Joshua Bolton.

May 1st, 1903.

HEYWOOD—*continued.*

June, 1903.

SEWAGE—

Average daily flow	709,133 gallons	Month's rainfall	1·62 inches.
Maximum daily flow	1,513,500 „	Rainfall	·66 „
Minimum daily flow	451,500 „	Rainfall	nil.

Average Analysis of Sewage.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	2·21	3·78	3·30 av. of 3
Albuminoid Nitrogen	·56	·89	·69 „ 3
Nitric Nitrogen	nil	nil	nil.
Chlorine	6·6	7·9	7·6 av. of 18
Oxygen absorbed from $KMnO_4$ in 4 hours	6·21	8·28	8·27 „ 18
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

TANK LIQUOR—

Average daily flow through the Tanks	709,133 gallons = to 22 hours 5 minutes in tanks.
Average number of Tanks in use	5½.
Amount of Chemicals used during month	10 tons 15 cwts.
Amount of Sludge dealt with during month	1,340 tons.

Average Analysis of Tank Liquor.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	1·78	2·42	2·29 av. of 3
Albuminoid Nitrogen	·28	·55	·42 „ 3
Nitric Nitrogen	nil	nil	nil.
Chlorine	6·8	7·0	7·5 av. of 18
Oxygen absorbed from $KMnO_4$ in 4 hours	2·02	2·56	2 83 „ 18
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

FILTERS—

Number of times Beds were filled during month	90.
Average duration of contact	2 hours.
Amount of Tank Liquor treated (gallons per cube yard per 24 hours)	167.

Average Analysis of Filter Effluent.

	Best.	Worst.	Average.
Ammoniacal Nitrogen	0·98	1·92	1·55 av. of 3
Albuminoid Nitrogen	·11	·23	·17 „ 3
Nitric Nitrogen	·41	trace.	·32 „ 3
Chlorine	6·6	7·0	7·3 „ 18
Oxygen absorbed from $KMnO_4$ in 4 hours	0·61	1·23	·96 „ 18
Dissolved Oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

REMARKS.—The Filter samples are fairly clear, with only slight traces of suspended matter.

July 1st, 1903. *Joshua Bolton.*

HEYWOOD—*continued.*

July, 1903.

SEWAGE–

Average daily flow - - - 760,358 gallons - Month's rainfall - - - - - 3·92 inches
Maximum daily flow - - - 1,615,875 „ - Rainfall - - - - - - ·65 „
Minimum daily flow (Sunday) 487,500 „ - Rainfall - - - - - - nil.

Average Analysis of Sewage.

——	Best.	Worst.	Average.

Mr. James H. Kershaw, F.C.S., Chemist and Manager of the Corporation Sewage Works, Rotherham, called in; and Examined.

Mr. James H. Kershaw, F.C.S.

10 May 1905.

21390. (*Chairman.*) You are Mr. James H. Kershaw, Fellow of the Chemical Society, chemist and manager of the Corporation Sewage Works, Rotherham?—Yes.

21391. You have come before us to-day to give evidence as to your experience in the treatment of sewage, with special reference to the Rotherham Sewage Works?—Yes.

21392. At Rotherham what is your system of sewage treatment, shortly described?—Sedimentation, followed by single contact, and then passed over land.

21393. What is the population draining to the Rotherham works?—About 53,000 or 54,000.

21394. What is the system of drainage? That is to say, is the storm water either wholly or partially drained into a separate system, and if only partially, to what extent?—It is mostly on the combined system. Only to a very small extent is the storm water kept separate from the sewage.

21395. Is there any infiltration of subsoil water into the sewers?—Yes.

21396. What is the water supply per head, and from what source does it come?—The water supply is 23·27 gallons per head. A portion of it is derived from local gathering grounds in an agricultural district, and the rest consists of moorland water, which we get from the Sheffield Corporation.

21397. Is it hard or soft water; if the former, what are its chief mineral ingredients?—The water we get from Sheffield is soft. Our local water is hard. As the hardness is mostly permanent, it will be due chiefly to the presence of sulphate and chlorides of lime and magnesia. A little iron is also present.

21398. What is the drainage area of the part of the town which is sewered?—About 1,000 acres.

21399. What proportion of the population use pail closets or middens and what proportion use water-closets?—The pail system is not used in Rotherham. Water closets are provided for about half the population, and midden closets for the remainder. Last year over 300 midden closets were replaced by water-closets.

21400. Has the flow of sewage to your works been gauged? If so, what is the average number of gallons delivered at the works per day of twenty-four hours in dry weather in winter and in summer?—The flow of sewage has only been gauged when the tanks have been refilled after sludging. The last measurements were made in October, 1904, when the flow was a little over 980,000 gallons in twenty-four hours.

21401. What is the maximum dry weather rate of flow, and at what hour does this occur?—That has not been determined.

21402. Has the minimum dry weather rate of flow been determined?—No.

21403. Can you say what has been the maximum wet weather rate of flow to the works, and during how many hours it has continued?—No.

21404. What storm overflows have you on your sewers, and at what rate or rates of flow do they come into operation?—There are several fixed sills or weirs in the sewers, but I have no information as to the rate of flow at which they come into operation.

21405. What is the largest number of gallons of sewage which have passed the last storm overflow and come to your works in twenty-four hours?—No observations have been made.

21406. Can you say what is the volume of water in gallons represented by the average yearly rainfall on the drainage area?—Our drainage area is about 1,000 acres, and in 1904 the total rainfall was 20·66 inches. This represents 468,723,750 gallons of water.

21407. Can you give the Commission an approximate statement as to the volume of sewage which comes to your works during the year, and the volume which passes over your overflows?—I should say we received during 1904 at least 365,000,000 gallons of sewage at the works. I have no knowledge as to the volume passing over the overflows in the sewers.

21408. If there be any infiltration of subsoil water into the sewers, does it occur regularly, or does it vary with the seasons or with the state of the weather; and can you give an approximate idea of the extra amount of liquid at one and another time entering the sewers from this source?—We get some subsoil water into the sewers, but I am unable to give any idea as to the amount. Some of the sewers are laid in very wet ground. The rate of infiltration will be influenced by the height of the ground water.

21409. How many gallons of trade effluents enter the sewers daily (twenty-four hours), and what is the nature of these effluents? If you have analytical figures, please give them?—The only trade refuse we have traced up to the present comes from one works, and amounts (so I am informed) to between three and four thousand gallons per twenty-four hours. This is a works where gas liquor is dealt with for the recovery of the ammonia it contains. The waste liquors from the still are discharged without any kind of treatment direct into the sewer. This refuse is heavily charged with soluble sulphides and sulphocyanides, etc., and at times the amount of suspended matter present is very considerable. Lime is used in the process to liberate the ammonia. I have examined a few samples of this particular refuse with the following results:—

All the samples gave an alkaline reaction with litmus paper, and had a phenolic odour. Many contained much greyish suspended matter which quickly settled, leaving a very clear, brown top water. The suspended solids consisted very largely of waste limey matter. HCl. added to the samples dissolved practically all the suspended matter, much H_2S being liberated.

	1.	2.	3.	4.
Solids in suspension	Very small amount	2628·0	344·0	2568·0
„ in solution	—	1836·0	180·0	2216·0
Total solids	1138·0	4464·0	524·0	4784·0
Which on ignition lost	290·0	172·0	128·0	748·0

Oxygen absorbed—4 hrs. test—at laboratory temperature, by sample as taken	438·0	967·0	71·5	1090·0
Oxygen absorbed—4 hrs. test—by liquid portion only	—	939·78	63·5	1080·0
Sulphocyanides and cyanates, calculated as NH_4SCN	200·0	150·0	25·0	250·0

There were estimated (approximately), colorimetrically, by means of an acid (HCl) solution of Fe_2Cl_6 and standard NH_4SCN.

21410. Has your authority framed any rules for the reception of trade effluents into sewers?—At present we have no rules or regulations dealing with the admission of trade refuse to our sewers.

21411. Do you find that the trade effluents interfere with the process of purification by reason of their quality, variations in composition, fluctuations of volume, or otherwise? If so, would you kindly tell us what your difficulties are?—I have explained the nature of the trade refuse in reply to Question 21409. I find the presence of that trade refuse in the sewage interferes very seriously with our results. It is not the volume so much as the strength or quality of the liquor that causes the trouble. At first when we began to get this refuse at the works many square yards of the surface of our filters were literally covered with worms that were evidently driven out of the material by the presence of something unusual in the tank effluent run on to the beds. These worms appeared to be in a very sickly condition. I allowed them to remain, and the filters were worked as lightly as possible for a few days, when almost the whole of the worms went down into the filter again. A recurrence of this takes place when the liquor comes down with a rush instead of in a steady stream. Our process consists of sedimentation, single contact (in coal filters), and finally the water is passed over heavy clay land. Sulphocyanides are nearly always present in the effluent, and as these compounds react in the oxygen absorption and the albuminoid ammonia tests the samples often come out badly on analysis, although I have never found them to become putrescent or deteriorate on keeping at laboratory temperature. As we do not get regularly satisfactory results with our present plant, I am constructing some experimental filters to ascertain the effect produced by second contact and continuous filtration.

Mr. James H. Kershaw, F.C.S.

10 May 1905.

21412. Can you say what the average amount of suspended matter in your sewage is in dry weather?—I have made no detailed estimations of the suspended matter present in our sewage; but from our two screens (one with three-quarter inch spaces and the other with half inch) and catch pits we remove from twenty-five to thirty one-horse loads of refuse and silt per month.

21413. What is the physical character of these solids?—This stuff consists chiefly of paper, solid excreta, rags, pieces of wood, lumps of grease and fat, vegetable waste, occasionally intestines, etc., from slaughter-houses, and in addition the sandy matter washed into the sewers from the roads. The suspended matter going forward to the tanks will consist of this class of material, only in a more broken up or disintegrated state.

21414. Can you give us average analyses of the sewage for the years 1903 and 1904 in summer and in winter?—The average results of sewage analyses are as follows:—

SUMMER, 1903.

	Oxy. Ab.	NaCl.	No. of Wet Days.	Inches Rain.
June	5·68	17·57	No record.	
July	6·5	19·5		
August	6·44	19·27

Mr. James H. Kershaw, F.C.S.

10 May 1905.

21415. Is it a "strong" sewage, and, if so, what characterises its strength?—Apart from the trade refuse before referred to, ours is not a strong sewage.

21416. Does its strength vary very much from hour to hour or on different days of the week, and, if so, do these variations affect the quality of your final effluent to a marked degree?—The strength of the sewage does not vary very much during the day, but some days it is stronger than others. These variations do not materially affect the final effluent.

21417. Have you any information as to the bacteriological condition of the sewage in dry weather and in storm times?—No.

21418. Are there any chemical poisons in the sewage? If so, what are they, and to what extent do they occur?—Yes. Sulphocyanides are almost always present. I have only recently commenced to estimate the amount present in our sewage, but I have had to do with sewage containing (approximately) sulphocyanides expressed as NH_4SCN, varying from traces up to 110 parts per 100,000.

21419. Is the sewage always alkaline?—Up to the present it has always been either neutral or faintly alkaline. I have never known it acid.

21420. Do you find that the amounts of suspended solids are increased or diminished in times of storm; and can you give the Commission the figures at the end of each hour during a storm of some hours' duration?—The amount of suspended matter in sewage is very largely increased in times of storm.

21421. How many years ago were your sewers laid, and do you know whether they have sunk much in places so as to allow solids to accumulate?—Our main system of sewers is practically new, having only been down six or eight years. One section at least of the old system of sewers which is at present in use has sunk to some extent, so that an accumulation of solid matter takes place.

21422. What is the character of the liquid part of the sewage in storm times? Perhaps you could illustrate this answer by analyses of the liquid portion of the sewage in dry weather and in storm times?—The following results were obtained from the partial analysis of samples taken during storms at overflows. As taken the samples were offensive, and contained much solid excreta. After removing the suspended matter by passing once through filter paper, the liquids were all fairly clear and not particularly offensive.

—	As taken.					After removing suspended matter.				
	(*a*)	(*b*)	(*c*)	(*d*)	(*e*)	(*a*)	(*b*)	(*c*)	(*d*)	(*e*)
Chlorine as NaCl	—	—	—	—	—	5·6	3·3	3·9	—	—
Free NH_3	1·12	—	1·44	1·08	1·16	1·17	1·12	1·12	—	—
Alb. do.	1·03	·76	·66	·98	1·08	·141	·14	·16	·13	·1
Oxygen absorbed (4 hours test)	8·13	5·6	—	—	—	1·37	1·41	—	—	—

Purification effected by removing the suspended matter: On the Alb. NH_3, 86%, 81%, 75%, 86%, 87%; on the oxy. absorbed, 83% 74%.

21423. In what way or ways do you think the sewage which comes to the works should be dealt with in storm times? Perhaps I should amplify this question a little. The usual requirements of the Local Government Board are, I understand, that any increase in flow up to three times the normal dry weather rate should be fully dealt with by the ordinary complete plant, and that a certain number of additional dilutions—up to a total of six—should be treated on special storm filters. Do you think these are proper requirements, or do you think they should be modified in any way? It is, I believe, often found that the storm sewage which first comes down to the works contains a largely-increased amount of suspended solids, and I should like to know whether you consider that your ordinary (dry weather) plant is exposed to damage in any way—as, *e.g.*, rapid choking—by having to deal with this amount of storm sewage, and whether you think it would be better to adopt some other treatment. Although the storm sewage, including the suspended solids, is a very polluting liquid, possibly the liquid portion alone is not very polluting, and this suggests that settlement of all the sewage arriving at the works in time of storms in tanks for a few hours, after, possibly, the addition of chemicals, might perhaps be a better plan of treatment than passing a portion of it through the ordinary plant, and the balance through storm filters. Would such settlement alone be sufficient for the whole of the sewage arriving at the works in times of storm?—The sewage is very foul for some considerable time after a storm arises. The damage likely to occur from choking of filters by passing storm sewage through the ordinary dry weather plant depends largely on the circumstances of the case. For instance, if the tanks are clean and contain comparatively little sludge, little or no harm should take place; but if, on the other hand, the tanks are dirty and about ready for sludging when the storm takes place, the extra rush and speed of the water through the tanks will set the sludge in motion, and a great quantity will be washed out and carried into the filters, thus causing choking up to take place. The method suggested in the latter portion of the question for settling the whole of the storm sewage in tanks would no doubt be very helpful and useful, but I am afraid such treatment alone, without some form of subsequent filtration, could not be relied upon to produce a satisfactory effluent.

21424. Do you think that the point at which storm overflows should come into operation should depend upon the configuration of the land—whether it is hilly or flat, etc., and upon the character of the surface soil geologically?—In hilly districts the storm sewage will pass away to the outfall works more rapidly than in flat districts, so that storm overflows might be allowed to come into operation sooner in the former than in the latter case.

21425. Should storm overflows be fixed or movable?—In my opinion storm overflows should be fixed.

21426. Do you think the number of dilutions at which storm sewage may properly be allowed to pass into the stream should be dependent upon the size and nature of the stream into which the storm sewage would pass? Is it possible, for example, that in some circumstances no injury to the stream would be caused by allowing overflows to come into operation when the increased flow was slight while in others this would not be the case?—Storm sewage discharged after the same number of dilutions would not have the same effect on all streams. If the overflow is into a large stream a smaller number of dilutions might be allowed before the discharge takes place than if it was run into a small stream.

21427. Could you give us an analysis of a typical sample of your road water during the early period of a storm?—No.

21428. Have you any information as to the bacteriological condition of the road water?—No.

21429. Do you consider that in certain circumstances this liquid should be purified?—Yes.

21430. What are your views as to the comparative cost and advantages of the separate and combined system of sewers?—I have no information on this matter.

21431. Is your sewage settled, and, if so, how; *i.e.*, by quiescent settlement or continuous settlement; and what length of time does it stay in the tanks or take to pass through, as the case may be? Would you kindly give an average analysis of the tank liquor, including the figures for suspended solids?—

Our sewage is settled on the continuous system, and takes about a day to pass through the tanks. The average tank effluent for 1904 took up 3·65 parts oxygen and contained 14·33 NaCl., and showed a purification over the sewage of 49·37 per cent. on the oxygen absorption.

21432. Have you data to show what proportion of the suspended matter in your sewage is settled in half-hour, one, two, three, four, five, six, twelve, and twenty-four hours, if the sewage is given quiescent settlement?—No.

21433. What time would be necessary for you to gain a good tank liquor containing, say, no more than six or eight parts of suspended solids per 100,000 from your sewage (without the addition of chemicals), by quiescent settlement and by continuous flow settlement?—That has not been determined.

21434. Do you prefer to use settlement tanks in series or in parallel?—I should say tanks used in series will give best results.

21435. In the case of continuous flow tanks do you think there is any advantage in the employment of baffling boards or walls?—I do not think baffle walls are of much service, but scum boards should be provided.

21436. How is the *sludging* of tanks done at your works, and what is the character of the sludge? Does any nuisance attend the operation, and, if so, is it serious? Have you means of storing sludge, or do you have to get rid of it as soon as it is removed from your tanks?—All the sludge from our tanks gravitates to a well inside the building, from which it is lifted by ram pumps into an overhead tank outside, then, if we wanted to press, it would flow back into the mixing vessel, and after liming, etc., it would go to the presses. Up to the present it has all been run from the overhead tank into lagoons. Whenever you have several thousand gallons of liquid sludge exposed there is bound to be some amount of smell, but at no time has there ever been anything that could be called a nuisance. We have no storage. The sludge has all to be got rid of at once.

21437. Should the heavy (road detritus, etc.) portion of the suspended matter in sewage be removed as a first operation, or do you think it better and more economical to let everything settle in the tanks, and subsequently to screen the sludge?—I prefer to keep the road detritus out of the tanks as much as possible.

21438. What is the manurial value of your sludge, and will farmers take it?—For some reason or other farmers seem to have a dislike to sewage sludge as a manure. There is much difficulty in getting them to give it a fair trial. We were fortunate last year in having a fair quantity taken away. Spread on our own grass land it improved the herbage very considerably. Potatoes also did well with it. An average sample of sludge being pumped into our lagoons in January gave the following results:—

H_2O - - - - -	85·0	per cent.
Organic and volatile matter -	7·4	,,
Mineral and sandy matter -	7·6	,,
	100·0	

Another sample of sludge after drying in a shed for a considerable time contained

Moisture - - - -	12·77	per cent.
Organic and volatile matter -	25·82	,,
Sand and mineral matter -	61·41	,,
	100·00	

Owing to the ready solubility of ammonia salts, the amounts found in sewage sludge are usually very small indeed. In my opinion very much less difficulty would be met with in the disposal of the sludge produced at many works if it could be reduced to the form of a coarse powder at anything like a cheap rate. In this condition it would be more convenient to handle and use, and probably these advantages would induce a more general desire to give it an extended trial.

21439. Are there any chemical poisons in the sludge?—I do not know of any.

21440. Do you find any nuisance from the treatment of sewage in settlement tanks? Have any complaints been made?—We get a slight smell from the tanks at times, but nothing serious. No complaints have been made.

21441. Have you had experience of the chemical precipitation of sewage?—Yes.

21442. Have you any reason to think that sewage from which the solids have been removed by the aid of chemicals is less easily purified by subsequent filtration than sewage from which the solids have been removed by settlement or by passage through septic tanks?—No.

21443. Have you tried various chemicals? Can you give any comparative data on the practical value and cost of different precipitants for the preliminary treatment of sewage, stating whether you are referring to the precipitation of strong or of weak sewage?—I am not able to give comparative data as to cost, etc., as my experience was with one particular process.

21444. What is the most effective way of adding chemicals?—The chemicals should be in solution before being added to the sewage.

21445. What is the character of the suspended matter in the liquor from the precipitation tanks?—The small amount of suspended matter present in the tank effluent would most likely consist chiefly of $Al_2(OH)_6$ and probably insoluble compounds of fatty acids derived from soap.

21446. Do you find it necessary to add further chemicals to the sludge before it can be dealt with? If so, for what reasons, and how are they added?—If sludge is to be pressed at anything like an economical rate it is absolutely necessary to mix lime with it. When sludge is pressed without lime it is very seldom that above two charges of good cake can be drawn from a press in one day, whereas when lime is used a press may be charged and drawn in about an hour. The lime helps to hold the water, and at the same time produces a hard, dry-looking cake. It is best to add the lime in the form of a fine dry powder to the liquid sludge in the mixing vessel before it passes into the forcing rams. However hard and dry a piece of fresh press cake may look and feel, it almost always will contain 50 per cent. or more of water.

21447. What was the manurial value of the sludge obtained by the chemical precipitation of sewage, and would farmers take it?—The sludge resulting from the precipitation process (with which I was at one time connected) after drying, etc., was sold. As there was a good demand for it I presume its manurial value in practice was found to be satisfactory.

21448. Did it contain any chemical poisons?—Not to my knowledge.

21449. Did you find any nuisance from the treatment of sewage in chemical precipitation tanks? Were any complaints made?—Under normal conditions no nuisance need be caused by precipitation tanks.

21450. As regards septic tanks, how should they be shaped?—An oblong tank and not too narrow seems to me to be the best shape, and arranged so that the sewage flows in the direction of the greatest length.

21451. Should they be divided into sections?—I do not think it is necessary to divide tanks into sections unless it is for the purpose of facilitating sludging.

21452. Should they be used in series or in parallel?—In my opinion it is better to use tanks in series than in parallel.

21453. Is a scum necessary or desirable?—I do not think a scum is absolutely necessary.

21454. Should the septic tank be closed in, and, if so, what advantages does a closed tank possess over an open one?—In my opinion no material benefit is to be derived by having the tank closed.

21455. What do you consider the best arrangement for the "feed" and "draw-off"?—I consider some form of submerged inlet and outlet desirable in order to prevent a mere surface flow.

21456. Do you think it desirable that the suspended solids in sewage should be removed as far as practicable before sewage is filtered? If so, what do you consider a practicable limit to get down to?—As much as possible of the suspended matter should be removed from sewage before it is applied to filters.

21457. In what way do you consider that the removal of the suspended solids can best be effected?—In order to get the sewage as free as possible from suspended matter it is essential that plenty of tank accommoda-

Mr. James H. Kershaw, F.C.S.

10 May, 1905.

tion be provided ; also that the flow should be steady. The tanks should be kept clean, *i.e.*, they should be emptied of sludge at frequent intervals.

21458. Have you any experience of any mechanical device or any special tanks for freeing tank liquor of suspended matter before delivering it to filters?—No.

21459. What other (if any) method of dealing with tank liquor before delivering it to filters do you regard as necessary or desirable?—If the conditions mentioned in reply to Question 21457 are fulfilled, a very good tank effluent would result, and it would not be necessary to treat it further before applying it to filters.

21460. As regards contact beds, is it advisable to construct the whole or any part of the interior of building material, or may you in some cases dispense with it entirely?—When the land is of a clay or stiff nature the only building material required in making contact beds is that used in the construction of the valve chamber. For making capacity measurements it is, of course, necessary that the filter material should be contained in a watertight enclosure ; in such cases building material is necessary.

21461. Do you find that within certain limits the depth of contact beds may vary without affecting their efficiency? If so, what limits do you think are permissible?—My experience has been with beds 3 ft. to 4 ft. deep. These give good results. I do not see why the efficiency should vary materially with beds of greater depth. The actual depth would be decided by the conditions and circumstances of the case.

21462. What do you consider is the most convenient size for a contact bed?—I consider that contact beds should be of such a size that they can be filled in one hour or less.

21463. What do you find to be the best filtering materials? What is the material (which can be had in practicable quantity) that, while efficient, is, in your experience, the least disintegrable in a contact bed?—My experience has been with beds filled with coal. This has done good work, and after nearly three years' working shows little signs of disintegration. Clean, well-burnt clinker is, in my opinion, as good as anything that can be used for filters. I am at present filling a bed with furnace coke, which I believe will prove a useful material. In certain districts "saggers" and other pottery waste would be available, and would do well in filters.

21464. What size should the filtering material be, and should it be graded in the beds?—Assuming tank effluent is to be dealt with, the body of a first contact bed might be filled with material passing through a 1¼ in. screen and retained on a 1 in. screen. For second contact, material from ⅝ in. to ⅛ in. could be used. I think it is advisable to have a layer of fine material (but free from dust) on the top, so that as much as possible of any suspended matter may be kept out of the body of the bed, and so that it can be removed at intervals, if necessary ; also that it may be exposed to the action of the atmosphere and the larger forms of low life.

21465. How should the bottom of the bed be constructed?—The floor of a contact bed should be fairly smooth or even, and should have a fall from every part to the outlet valve. Perforated pipes or draining tiles should be arranged at intervals over the floor, and the whole covered with a layer of rough material to carry the smaller material used in the body of the bed.

21466. Do you think it generally desirable that sewage should be subjected to some form of tank treatment before it is put on contact beds?—It is very necessary that sewage should go through some form of tank treatment before it is put on contact beds. Otherwise they will choke up rapidly.

21467. What periods of filling, standing full, emptying, and standing empty do you consider best in practical working for primary beds and for secondary beds?—I consider three fillings per day (worked in cycles of eight hours) is enough work to put on contact beds, and that there should be one hour for filling, two hours standing full, one hour emptying, and four hours' rest. No material benefit appears to be produced by a much longer contact than two hours.

21468. How should contact beds be filled and emptied?—I have not observed any difference in the results obtained from filters filled by means of half pipes laid on the surface of the material and others where the water has been run direct on to the material. If circumstances permitted, I would like to see the effect produced by filling a contact bed by means of a spray or sprinkler, with the idea of getting the water well aerated before it gets into the bed. In emptying, I think it best to start steadily till about a foot or so has run off, when the valve should be opened to the full extent and kept open till the filter is filled again.

21469. Have you had any experience of automatic gear for filling and emptying contact beds?—I have no personal experience of automatic gear for filling and emptying filters.

21470. Is one contact sufficient for the conversion of certain tank liquors into a satisfactory effluent? If so, please state in precise terms (*i.e.*, by analytical figures) of what tank liquors you are speaking and what effluent you are regarding as satisfactory?—Single contact cannot be relied upon to regularly produce satisfactory results. In 1903 the average oxygen absorbed by the tank effluent was 2·34, whilst the filtrates from single contact absorbed ·96 parts of oxygen, the purification effected being 59 per cent. In 1904 the tank effluent absorbed 3·65 parts of oxygen and the filtrates 1·49, the purification being 59·18 per cent.

21471. Is the loss of capacity in contact beds in direct proportion to the volume treated and the amount of suspended solids contained in the liquid which is put into the bed, or to the fineness or coarseness of the material of the bed, or on what does it depend?—I should say the loss of capacity is in proportion to the volume of the liquid treated and the amount of suspended matter it contains. The quality of the suspended matter must also have some influence, for if it consists of inorganic or sandy matter it will remain permanently in the bed, and tend to choke it unless it passes out in the effluent. There is less danger of choking permanently from the organic portion of the suspended matter when left in the bed. In this case there is the possibility of the organic matter being broken up and consumed, to some extent at least, by biological and other means, thus causing a diminution in its bulk, and consequently lessening its power to diminish the water capacity. Then the grade of the material must have much to do with the loss of capacity. It is obvious that a filter made of fine material will remove more suspended matter from a given liquid than one made of coarser material, and the more suspended matter left in the bed the greater the loss in its water capacity.

21472. Can the material of a clogged bed be washed, and, if so, how can this best be done, and at what cost per cubic yard?—I have had no experience of washing the material from a filter, but I should say it is possible.

21473. How can the capacity of contact beds be best maintained?—The water capacity of filters is best maintained by (a) feeding them with a liquid as free as possible from suspended matter ; (b) not overworking them ; (c) thorough draining off ; (d) giving them a complete rest as often as possible ; (e) when the surface of the bed requires loosening or forking over, it should be done carefully, as it must tend to disintegrate the material to some extent.

21474. What is the average analyses of your single contact and double contact effluents?—We have only single contact. The average filtrates for 1903 and 1904 were as follows :—

	No. of samples.	Oxygen absorbed.	NaCl.
1903	175	·96	13·09
1904	153	1·49	14·6

21475. What is the number of gallons of liquid treated daily per cubic yard of filtering material in your beds?—Last year the average daily amount of liquid treated per cubic yard of material would be about 82·6 gallons by our single contact beds.

21476. Do you find any chemical poisons in the final effluent?—Sulphocyanides are usually present.

21477. What is the average amount of suspended matter in the effluent? Does most of this suspended matter come out with the first flush or not?—The amount of suspended matter in the filtrates has not been determined. The first flush usually contains

most of the suspended matter, but the drainings contain some. The bulk of the discharge is very free from suspended matter.

21478. To what extent do you find that the organic matter of the suspended solids issuing in the effluent from a contact bed is different from the organic matter of the suspended solids going on to that bed?—No observations have been made on this point. The suspended matter from our filter appears to contain some gritty matter, but the bulk of it consists of a dark-coloured growth, which I believe collects in the drain pipes in the beds.

21479. Is the first flush of effluent from the beds ever putrescible?—This has not been determined.

21480. Do you find that by increasing the number of fillings in storm times or other times the amount of suspended solids is increased?—No material visible increase has been noticed.

21481. May contact beds in times of storm be used as streaming filters without detriment to their customary efficiency?—I have no experience of using contact beds as streaming filters in storm times.

21482. Have you made any experiments which throw light upon the action of contact beds when full and when resting?—No.

21483. Have you made a study of the conditions of aeration of contact beds?—No.

21484. Do you find any nuisance from the treatment of sewage on contact beds? Have any complaints been made?—There has been no nuisance arising from the working of our contact beds. No complaints have been made.

21485. Have you had any experience of continuous or percolating filters?—I have two filters, each 50ft. diameter and 4ft. 6in. deep, fed by revolving sprinklers, but as they have only been working a few weeks my experience is too short to enable any decided opinions to be expressed on the working, etc., of this type of filter. The filtering material is coal. Open septic tanks precede the filters. I will give the results obtained up to the present from these filters. The filtrates were examined after the suspended matter had been removed. Samples were then bright and clear, and had a fresh, earthy odour. The analyses are as follows:—

Tank Effluents. Oxygen absorbed.	Filtrates. Oxygen absorbed.	Nitric N.	Purification.
5·4	2·45	—	54·6 per cent.
6·25	·8	·028	87·2 „
9·11	1·66	—	81·7 „
7·0	1·06	—	84·8 „
7·48	1·46	—	80·4 „
5·1	1·24	·233	75·7 „
3·58	·83	·908	76·8 „
6·65	1·34	—	79·8 „
—	1·13	·25	—
Average = 6·32	1·33	—	77·6 „

21486. Do you find that the chance of nuisance is any greater with one form of filter than with another? Does the risk of nuisance depend on the kind of sewage which is being treated or on the nature of the preliminary treatment to which the sewage has been subjected?—I should say filters fed by means of jets, sprays, or sprinklers are more likely to cause a nuisance than contact beds fed in the ordinary manner. The risk of nuisance depends to a very large extent on the preliminary treatment the sewage has been subjected to. For instance, strongly septic tank effluents when sprayed or sprinkled will most likely give rise to some amount of nuisance. Our contact beds are fed with open septic or sedimentation tank effluent. I have found no nuisance from them.

21487. Could you express an opinion as to how the number of gallons would vary with variations in the strength of your tank liquor, and on what figure or figures you would rely for defining the "strength" of your tank liquor?—Taking the oxygen absorbed as the standard of strength, I have found that our beds will bring about a purification usually of from 50 to 60 per cent. in the tank effluent run on.

21488. Have you had any experience of storm water filters?—No.

21489. Can you express any opinion as to whether storm water filters would lose any of their efficiency by being used intermittently at long intervals?—Judged from the experience of getting contact beds into condition at first, I should say that storm filters cannot be regarded as anything but strainers if used at long intervals, and if the dilution required by the Local Government Board is insisted upon, very little more than straining should be required.

21490. Have you any practical suggestions to make for disposing of sludges?—As regards sewage screenings, seeing that the greater portion of the material removed from the screens at sewage works consists of organic matter, the most effective method of disposal is by burning in some kind of destructor, or the stuff may be tipped and covered with earth so as to prevent nuisance. The material from detritus tanks consisting of sand and gritty matter does very well for lightening heavy land, otherwise it can be tipped, when by exposure it rapidly gets purified, losing its offensive black colour and becoming like ordinary road grit. Sludge from precipitation, septic, and settlement tanks is best pressed in order to keep the bulk within reasonable limits. As much as possible of all forms of sludge should be disposed of to farmers. In some cases it might be admissible to drain the sludge in lagoons instead of pressing.

21491. Do you find that some methods of disposing of sludge are more likely to cause nuisance than others?—Press cake and sludge containing lime, when tipped in a heap, is very liable to heat, and becomes a nuisance owing to the peculiar sickly odour it gives off. Lagoons are usually strongly condemned, but up to the present all our sludge has been disposed of by this method without nuisance.

21492. What, in your opinion, constitutes a good effluent?—A good effluent is one in my opinion which is not offensive in appearance or smell, and is not liable to become, when discharged into a stream, changed in appearance or smell. Nitrates should be present, and it should not yield more than from ·1 to ·15 parts Alb. NH_3 per 100,000, nor absorb more than 1 to 1·5 parts oxygen in the four hours' test. It should

Mr. James H. Kershaw, F.C.S.

10 May, 1905.

not become putrescent or offensive on keeping, and it should be free from suspended matter.

21493. Do you consider the type of effluent from a contact bed is superior or inferior to the type of effluent from a percolating filter?—I cannot express a definite opinion on this point, as I have only been using continuous filters for a short time. Percolating filters appear to produce better nitrification than single contact beds.

21494. What test or tests do you chiefly rely upon in judging of the quality of an effluent, and for what reasons?—As a routine test I always use the four hours' oxygen absorption test at laboratory temperature, because of its easy application, and as I find that if our outfall samples come out satisfactorily to this test they never deteriorate or become putrescent on keeping. Nitrate and alb. ammonia determinations are also made from time to time.

21495. Have you tried the "aeration" test, *i.e.*, the rate at which dissolved oxygen is taken up by an effluent?—I have not as yet used the "aeration test."

21496. Is one standard for all effluents passing into non-potable streams possible and desirable?—I do not think it practicable or desirable that one standard should be fixed for all effluents passing into non-potable streams.

21497. How should a plurality or series of standards be formulated? What amount of suspended matter would you allow in an effluent, and what are your reasons?—As one general standard is not considered desirable, I should say a combined standard of, say, 1·5 parts alb. NH_3, or 1·5 parts oxygen absorbed four hours in addition to the presence of nitrates might be found equitable. It is a difficult matter to keep effluents entirely free from suspended matter, but I should say 2 or 3 parts per 100,000 might be allowed.

21498. What is your experience of the effect of storm water upon filters of various sorts?—I have not noticed any special effect produced by storm water on our contact beds beyond the danger there is of carrying more suspended matter out of the tanks on to the beds owing to the increased rate of flow.

21499. How far do you consider it advisable for a sewage installation to be worked automatically?—No sewage installation of any dimensions should be worked automatically. Private residences and small villages might be so worked if seen every day, but installations for 500 population and upwards should receive constant attention. The greater the attention the better the effluent, and the less liability to nuisance.

21500. Have you made any systematic observations as to the effects of discharging effluents of known volume and known composition into ditches, canals, brooks, or rivers of approximately known volume? The main points I refer to are nuisances from smell, deoxygenation of the water, encouragement of vegetable growths either of the nature of sewage fungus or of green weeds, and damage to fish?—After examining a large number of samples from our single contact beds it was found that they could not be relied upon to produce a filtrate requiring not more than one part of oxygen in the four hours' test, but the further observation was made that, on these samples being re-examined after keeping a few days, a very marked improvement was almost always found to have taken place. This may, in my opinion, be due chiefly to two probable causes—firstly, a continuation of the biological action commenced in the filter and continued by the organisms carried out of the bed and present in the filtrate; or, secondly, the improvement may be due to the method we use for emptying the filter, viz., by means of a compressed air lift. A very large volume of air is thoroughly incorporated with the water, and possibly a sufficient amount of oxygen may pass into solution to bring about wholly or in part the diminution in the amount of oxygen required in the absorption test applied after the samples have stood some time. This is a point I hope to go into as soon as circumstances allow. We have several depressions on our land which always stood full of water even before the works commenced. With the object of utilizing the above observation I decided to make use of these ponds for the further purification of a portion of our single contact water. They were connected together by means of ditches; in places the water was made to spread out and flow in a thin sheet, so as to get as much exposure as possible. Altogether, we shall have an area of six to eight acres of water regularly exposed in these ponds. A public footpath runs through the largest one, connecting pipes having had to be laid. The water from this pond goes direct to the outfall. I never intended using the ponds as much as they have been, but as a considerable improvement was effected their use was continued. Largely owing to this arrangement, we were enabled to do without a night shift of men for quite twelve months. On an average about 150,000 gallons per day would be passed through the ponds, the outlet being always open and continuous, Owing to the publicity of the site great care had to be used in the working. I found the weather had a great influence over the water in its appearance. With regard to the question of nuisance, unless the thing is very carefully watched and worked there is undoubtedly a danger of a nuisance arising. At times there has been a distinct vegetable or sea-weedy odour, but it has never amounted to a nuisance. No determinations of dissolved oxygen have been made, but the use of this test is about to be adopted. When the ponds have been worked too hard or fed with bad water I have often noticed sewage fungus begin to grow. This disappears with resting. Normally a large amount of a green weed grows, and sometimes the whole surface of the water will be covered in places with it. There are no fish in the ponds. I find that this method of treatment brings about a reduction of at least 50 per cent. in the oxygen absorption figure. Very little nitrification appears to take place. I do not advocate the use of ponds, but as additional filters were not obtainable the natural features of the site were used in what appeared likely to prove a useful manner.

21501. What are your views with regard to the quantitative determination of the "strength" of a sewage, tank liquor, etc.?—I think the results of the four hours' oxygen absorption and the alb. ammonia determinations are the two most useful items to have in order to form an idea as to the strength of sewages, etc.

21502. Are there any other points on which you would wish to speak at this stage?—I should like to make some observations on the effect of keeping samples of effluents. It is a matter of common knowledge that many samples of effluents develop a green growth on keeping. This is taken as a rough indication that the sample is of good quality. In order that this green growth may develop it is essential that the sample be exposed to the light. I have taken fresh samples of effluents, and, after dividing, put one in a dark cupboard and allowed the other to be freely exposed to the light. In no case has the dark sample (in one instance samples were kept 225 days) developed the growth, but in the other it has nearly always shown itself. It has also been noticed that this growth may develop rapidly. In one case I found it to be very distinct in five hours after the sample had been put into the bottle. If the bottle stands near a window I have found that the growth develops first and attaches itself to the side of the bottle next the window. This development goes on till the whole contents of the bottle become quite muddy with the green suspended matter. Usually a "sea-weedy" odour is developed at the same time. In addition to the above I have observed for a long time that this green growth when pretty strongly developed is always accompanied by the production of an alkaline reaction in the sample. From inquiries made, I believe this is the first occasion on which this observation has been noted. I have never found a sample to develop this alkalinity in the absence of the green growth, consequently samples kept in the dark do not turn alkaline. The alkalinity is most readily shown by adding a few drops of phenolphthalein to the "green sample," when if the alkali is present the liquid turns red or pink, according to the amount present. I have not yet proved what this is due to, but that it consists of a volatile alkali (ammonia?) at least to some extent the following experiments will show:—Three samples were taken from a large number, all more or less green, and 100 c.c. of each were titrated with deci H_2SO_4 to Phenolphthalein (P.T.); then methyl orange was added, and the titration continued till just acid. A further 100 c.c. of each sample was then evaporated to dryness. The residue was taken up with fresh distilled water of proved neutrality, and titrated as before.

100 c.cs. taken.	1.	2.	3.
Age of Sample in days	55	49	17
C.c.s. $\frac{\text{deci.}}{H_2SO}$ required to P.T.	1·2	1·4	·8
Then do. more required to M.O.	1·2	1·2	2·8
C.c. $\frac{\text{deci.}}{H_2SO_4}$ required by total alkali	2·4	2·6	3·6

100 c.cs. after evaporation.	1.	2.	3.
C.c.s. $\frac{\text{deci}}{H_2SO_4}$ required to P.T.	¼ drop	Nil	1 drop
Then do. more required to M.O.	1·2	1·2	1·2
C.c. $\frac{\text{deci}}{H_2SO_4}$ required by the "non-volatile" alkali	1·2	1·2	1·2

It seems rather remarkable that the non-volatile alkali should show the same amount in samples taken so widely apart. As to what the precise action is, or how this alkalinity is brought about, I am unable at present to explain. I should also like to make some observations on the disappearance of sulphocyanides in sewage on keeping. Having at one time to deal with a sewage which was liable to be irregularly charged with waste gas liquors, a large number of samples were examined. On one occasion sulphocyanides equal to 110 parts NH_4SCN per 100,000 were found to be present in the sewage on its arrival at the works. Some of these samples were kept under notice for long periods, and the following observations made:

Sample.	NH_4 SCN present.	All sulphocyanides disappeared on keeping.	Had sample developed a green growth?
Sewage 1	7·3	19 days	Yes
,, 2	3·4	65 ,,	Yes
,, 3	29·	173 ,,	No
,, 4	52·5	192 ,,	Yes
,, 5	4·	191 ,,	No
,, 6*	12·	161 ,,	No

Sulphocyanides when present in sewage will disappear on keeping, providing a sufficient length of time is allowed. A green growth usually develops, and also an alkaline reaction, but this is not an essential factor in the change that takes place. In my opinion, the most probable explanation of this action is that the change is brought about by biological agency. There appears to be no regularity or fixed rate at which this disappearance takes place. This may probably be due to the difference in the biological contents of the various samples. In order to deal efficiently with sewage mixed with this class of refuse, it is most important that it should be admitted to the sewer in a steady stream, and never in large volumes at one time. It is known that contact beds in good condition are capable of breaking up these compounds to a considerable extent. Experiments are about to be commenced to ascertain the effect produced by treating a liquid containing sulphocyanides on a percolating filter.

21503. On Question 21423 I am not quite sure from your answer whether or not you think it advisable as a general rule that storm sewage should pass through the ordinary plant?—It has to do so at our place; we have to pass it through at our works.

21504. But do you think it is objectionable?—It is sometimes, as I state in my reply here.

21505. Now, with regard to Question 21431. Can you tell me how many parts of suspended solids per hundred thousand you get in your tank effluent?—I cannot; I have never estimated it.

21506. (*Colonel Harding.*) In question 21422 you speak about the character of the storm waters, and you say that the impurities are largely due to suspended matter?—Yes.

21507. And you give an interesting table, from which it appears that the withdrawal of suspended matter from storm waters gives by itself a purification of from 75 to 87 per cent.?—Yes.

21508. Later on, in your answer to Question 21423 you express the opinion that sedimentation of storm water alone without some sort of subsequent filtration could not be relied upon to produce a satisfactory effluent?—Yes.

21509. But a purification of 87 per cent., leaving a liquid which itself is very dilute, does not seem to require very much additional treatment beyond the sedimentation?—No, it does not.

21510. But you think it would be better for some additional treatment?—You see, when these particular samples were taken the storm might have been on for some considerable period.

21511. Arguing simply on the facts you have put before us, it appears that the albuminoid ammonia after sedimentation of these storm waters is represented by only 1·3 per hundred thousand?—Yes. It should not require very much more besides sedimentation, but I do not think sedimentation alone is really satisfactory. I do not think it can be relied upon to produce a regularly satisfactory result.

* No diminution took place after keeping for 89 days and there was no green growth formed. At this point sample was divided (*a*) and (*b*). Some "green growth" from another sample was put into (*b*) and allowed to stand. On keeping 72 days longer I found that (*a* contained only a mere trace of sulphocyanide and that (*b*) was quite free.

Mr. James H. Kershaw, F.C.S.

10 May 1905.

21512. It would give very good results, though not in your opinion thoroughly satisfactory?—Yes.

21513. What additional process would you suggest besides sedimentation?—I have never worked any storm filter, but I should think single contact.

21514. You have no experience?—We have no storm filters; no.

21515. I rather gathered that from your first answer to the Chairman when you said you have not any percolating filters at all?—That is so.

21516. But do you not at Question 21485 make some reference to percolating filters?—I can explain that.

21517. You say: "I have two filters, each 50 ft. diameter and 5 ft. deep"?—We have two works. We have one at a little village about four miles from our main works. We started it only two or three months ago. I was referring to our main works.

21518. Then you have some personal experience of percolating filters?—Very slight.

21519. These two filters have been working for so short a time that you feel that you ought not to say much about it?—I would not like to say much on that point.

21520. The analyses which you have given us were after the withdrawal of suspended matter from the filtrates?—That is so.

21521. Can you tell us how much suspended matter goes on to the filters?—I cannot.

21522. We gather that you have not long been appointed to these works, and have not as yet had time to get into full routine, but appreciate the importance of noting the amount of suspended matter?—Yes.

21523. In Question 21502 you touch upon an interesting point, and that is that the development of green growths in the samples kept in bottles is dependent upon the presence of light?—Yes.

21524. Probably your experience of percolating filters has scarcely been long enough to enable you to tell us whether you have any trouble with fungoid growths on the surface of your percolating beds?—I do not think we have had any fungoid growths, but we have had the thing clogged up with suspended matter.

21525. Are you sure that it was suspended matter only?—Largely.

21526. You have not been able to judge whether it was not to some extent fungoid growth?—I have not examined it closely for that. I was satisfied that it was really the sludge.

21527. It might be worth your while to look into that, and to see whether the development of that growth was dependent upon the action of light. It would be an interesting experiment for you as you appear to be interested on this particular point, to cover a part of the percolating bed—to put a little roof over it or something of that kind to keep the light away—and see whether the development of the fungoid growth, like the green growth to which you call attention, is really dependent upon the presence of light?—Yes.

21527*. (*Dr. Stafford.*) In Question 21474 the difference between your analyses for 1903 and 1904 of the oxygen absorbed test seems very large; what is the explanation?—The only explanation I can give is that we had more sewage connected up—more connections had been picked up during the intervening period.

21528. That makes the difference, you think, in the particular samples?—I should think so.

21529. The difference is very large?—Those are the averages for the whole year.

21530. But you are comparing 1903 and 1904?—Yes.

21531. And the difference is between ·96 and 1·49—a very great difference?—That is the only thing I can put it down to—that we had a stronger sewage to deal with.

21532. (*Major-General Carey.*) Your dry weather flow, based on the water supplied, amounts to 1,232,250 gallons per diem, does it not?—I believe it is somewhere about that.

21533. In October, 1904, your flow was a little over 980,000 gallons, or only 18 gallons a head. Is there any reason for that reduction?—The reason is that we were not getting it all down to the works; a part of it was going to the river direct.

21534. I do not quite understand?—Some of the crude sewage that we ought to have got at the works was not coming to the works.

21535. Is the capacity of your precipitation tanks and contact bed based upon the larger volume?—No, it is on a million gallons per day; it is an approximation to a million gallons per day.

21536. Your tank capacity?—The tank capacity is 900,000. There are six tanks with a capacity of 150,000 gallons each.

21537. Are you able to pass three times the dry weather flow?—As a matter of fact we pass pretty well everything that comes down to the works in storm times through the tanks.

21538. I mean, are you able to pass three times the dry weather flow through the tanks and then on to the contact beds without injury to the bed?—We do it, but I do not think it is an advisable thing, because you are bound to have much more suspended matter washed out of your tanks on to the beds.

21539. How do you treat the remainder?—If it is a very big storm we run it direct on to the land.

21540. How much land have you?—I think, roughly, there are about 10 acres that we can get it on.

21541. But how much land have you altogether?—We have 90 acres in the plot altogether, but we cannot use all that for filtration purposes owing to the formation of the place. There is very little underdraining, and it is very heavy clay soil.

21542. Throughout?—Yes; it can hardly be reckoned to do it any good except by exposure.

21543. Do I understand that all over three times the dry weather flow is put on to this land?—No.

21544. Do you put it on the storm beds?—No, we have no storm beds.

21545. How do you treat it?—We send everything through the tank unless it is a very heavy storm, when we pass some on to the land direct. We do not measure it in any way.

21546. Do you not measure how much you pass on to the contact beds and how much on to the land?—No.

21547. As I understand, the effluent from your contact bed has not been satisfactory?—It is very good for a single contact effluent.

21548. But it would not pass the Mersey and Irwell standard, for intance?—Not regularly.

21549. Are your replies to Questions 21450 to 21455 based upon actual experience in septic tank treatment?—No; that is a general opinion that I hold.

21550. Have you had any real experience of septic tank treatment?—No, I cannot say that I have.

21551. (*Sir William Ramsay.*) In your answer to Question 21411 you say that sulphocyanides are nearly always present in the effluent. Have you estimated the amount of sulphocyanides in the effluent?—Yes, in answer to Question 21418.

21552. You say you have only recently commenced to estimate the amount in the sewage, and that you have had to do with sewage containing approximately sulphocyanides up to 110 parts per hundred thousand. Have you ever estimated it in the effluent?—Not at Rotherham.

21553. Is it your impression that much comes through; is it reduced at all by the filtration process?—I think it is. That is by comparative tests, not actual determination.

21554. Your opinion is that it is reduced by filtration?—Yes.

21555. I do not know whether you have been asked about the order in which you prefer to use settlement tanks. You say that you think tanks used in series give the best results, have you any reason for that opinion?—I have not worked the quiescent system. That is a general opinion I hold.

21556. When you speak of the smell from the tanks as being nothing serious, are there any houses near?—There are only the workmen's cottages.

21557. And they are not likely to complain?—Of course not. I would like to add that we have remark-

ably little smell—nothing you could really complain of. We have two public footpaths across the works.

21558. But the people who cross those paths do not complain?—Not that I know of.

21559. In answer to Question 21467 you say that no material benefit appears to be produced by a much longer contact than two hours on the contact beds. Is that the result of your experience? Have you experimental data to support that?—I have no regular series of analyses, but we have tried it; sometimes the beds have been held up for two, three, or four hours.

21560. But you do not think there is any material benefit in a longer contract?—I have not noticed any.

Mr. James H. Kershaw, F.C.S.

10 May 1905.

21561. Then, in answer to Question 21500 you speak of ponds which were connected all together by means of ditches. Are they deep ponds or shallow?—They are rather shallow.

21562. About what depth?—I do not think they are more than three or four feet at the deepest parts. They are just natural hollows in the land.

ROTHERHAM.

Appendix to Evidence of Mr. James H. Kershaw.

Tables showing average analyses of sewage, tank liquor, filter effluents, and land effluents, January, 1903—December, 1904.

PROCESS OF TREATMENT:

Sedimentation Tanks, Single Contact Beds, and Land.

Nitric Nitrogen	—	—	—
Oxygen absorbed from $KMnO_4$ in 4 hours	·43	3·74	1·5
Suspended Solids	—	—	—

Number of samples analysed for the average = 34.
Purification from Sewage to Outfall = 87·2 per cent.
An admixture of a trade refuse is the cause of these high figures.
During the year 313 loads of refuse and silt were removed from the screens and catchpits at the Works.
Gas liquor again present in the Sewage.

January 18th, 1905.

Jas. H. Kershaw, F.C.S., Chemist and Manager.

SUMMARY FOR 1904.

1904.	Loads of Screenings and Silt.	Gallons of Sludge Pumped.	Sewage.			Tank Effluent.				Filtrates.					Outfalls.						Number of Wet Days.	Total Rainfall in Inches.	Number of Filter Fillings.
			Number of Samples Examined.	Chlorides Expressed as Sodic Chloride.	Oxygen Absorbed (four hours' test) at Lab. Temp.	Number of Samples Examined.	Chlorides as NaCl.	Oxygen Absorbed.	Purification on the Sewage.	Number of Samples Examined.	NaCl.	Oxygen Absorbed.	Purification on the Tank Effluent.	Purification on the Sewage.	Number of Samples Examined.	NaCl.	Oxygen Absorbed.	Purification on the Filter.	Purification on the Tank Effluent.	Purification on the Sewage.

James H. Kershaw, F.C.S.,
Chemist and Manager.

Mr. K. F. CAMPBELL, M.INST.C.E., called in; and Examined.

21563. (*Chairman.*) You are Mr. K. F. Campbell, Member of the Institute of Civil Engineers and Borough Engineer of Huddersfield?—Yes.

21564. You have kindly come here to-day to speak of your experience of the treatment of sewage, with special reference to the Huddersfield Corporation Sewage Works?—Yes.

21565. What, shortly described, is your system of sewage treatment at Huddersfield?—We have two systems. One is the open septic tank followed by percolation filters for filtration, and the other is chemical precipitation followed by filtration on the system known as double contact.

21566. What is the population draining to the Huddersfield works?—100,000.

21567. What is the system of drainage? That is to say, is the storm water either wholly or partially drained into a separate system, and if only partially, to what extent?—The system is the combined one.

21568. Is there any infiltration of subsoil water into the sewers?—Yes.

21569. What is the water supply per head, and from what source does it come?—The water supplied by the Corporation is as follows: For domestic purposes, 14 gallons per head, for trade purposes, 9 gallons per head. There is also a fairly large quantity of water used from wells and borings. The water is supplied from the Corporation reservoirs, the drainage area of the reservoirs is chiefly moorland, or high mountain pasture and millstone grit formation.

21570. Is it hard or soft water?—Soft.

21571. What is the drainage area of the part of the town which is sewered?—About 10,000 acres.

21572. What proportion of the population use pail closets or middens, and what proportion use water-closets?—Seventy per cent. use pail or midden and thirty per cent. use water-closets.

21573. Has the flow of sewage to your works been gauged? If so, what is the average number of gallons delivered at the works per day of 24 hours in dry weather in winter and in summer?—Yes, the flow has at times been gauged. Records in the dry summer of 1904 show an average of about 7,000,000 gallons. In winter the average dry weather flow is about 9,000,000 gallons per day.

21574. What is the maximum dry weather rate of flow, and at what hour does this occur?—From 7,000,000 to 12,000,000 gallons during working days, usually greatest at mid-day.

21575. What is the minimum dry weather rate of flow, and at what hour does this occur?—From 3,000,000 to 6,000,000 gallons on Sundays and week nights. Usually lowest about midnight.

21576. What is the maximum wet weather rate of flow which you have observed coming to the works, and during how many hours has this continued?—At the rate of 53,000,000 gallons per day for a very short time.

21577. What storm overflows have you on your sewers, and at what rate or rates of flow do they come into operation?—Storm overflows are fixed on the branch and main intercepting sewers, and come into operation in most cases when the sewers are running over half full. The sewers are constructed to carry $\frac{1}{8}$ inch rainfall in eight hours before the storm water overflows commence to act. A few of the storm overflows are of the kind known as leaping weirs, and these are arranged in accordance with the gradients of the sewers on which they are fixed.

21578. What is the largest number of gallons of sewage which have passed the last storm overflow and come to your works in 24 hours?—The highest recorded flow has been at the rate of 53,000,000 gallons per 24 hours. The quantity registered for the full 24 hours during which the storm lasted being 18,786,000 gallons (measurements were taken every hour and the average taken).

21579. Can you say what is the volume of water in gallons represented by the average yearly rainfall on the drainage area?—Yes, 7,474,896,000 gallons per annum.

21580. Can you give the Commission an approximate statement as to (a) the volume of sewage which comes to your works during the year; and (b) the volume which passes over your overflows?—The quantity of sewage which comes to the works is 9,000,000 gallons per day, equals 3,285,000,000 gallons per year. I estimate the quantity discharged by the storm overflow at about 1,200,000,000 gallons per year.

21581. Does the infiltration of subsoil waters into the sewers occur regularly, or does it vary with the seasons or with the state of the weather; and can you give an approximate idea of the extra amount of liquid at one and another time entering the sewers from this source?—This varies with the weather and the state of the ground. There is besides subsoil water a considerable quantity of clean water from other sources entering the sewers, stream waters, overflows from reservoirs, condensation water, etc. The amount of extra water entering from these sources is on an average about 2,500,000 gallons per 24 hours.

21582. How many gallons of trade effluents enter the sewers daily (24 hours), and what is the nature of these effluents?—Approximately, four million gallons per 24 hours, of which three millions are derived from processes of woollen manufacture, wool scouring, the nature of which is chiefly soapy dye liquors, and one million derived from other trades, such as cotton spinning and washing, brewing, curriers, gas works, and chemical works.

21583. Has your authority framed any rules as to the reception of trade effluents into sewers? If so, what are they?—Rules have been framed, but up to the present the Corporation have been unsuccessful in putting these in force. They are as follows:—

(1) Volume.—The volume of waste waters shall be reduced as far as practicable, as for example, by keeping condensing water and surface water out of the drains.

(2) All trade waste waters except suds shall first be passed through coke filters on the downward and upward principle before the Corporation can receive the effluent into the sewer.

(3) Suds in all cases shall be treated for the removal of grease, and after sufficient time has been allowed for the precipitation of the grease, the liquid shall be drawn off by means of a floating arm, and after passing through a coke filter on the downward and upward principle, may be discharged to the sewer.

(4) The time of discharge shall be so regulated by the Corporation that all the trade waste shall not discharge into the sewers at the same time.

(5) A manhole or other opening shall be provided to the satisfaction of the Corporation, on the line of drain between the mill and the Corporation sewer, and the officers of the Corporation shall have the right to take samples at this point, and to inspect the tanks at any reasonable time.

(6) Before commencing any works for the treatment of trade waste waters, plans shall be submitted to the Corporation for their approval.

(7) In the event of any of the foregoing conditions not being complied with, the liberty to discharge trade effluents shall be *ipso facto* suspended so long as such non-compliance continues.

21584. Do you find that the trade effluents interfere with the process of purification?—Yes, they render the purification of the sewage more difficult. The nature of the liquids, the chief part of which are soapy dye liquors, makes their purification difficult, the trade refuse being not so amenable to treatment as domestic sewage. The sewage, too, is very variable in composition and in volume, due to the irregular manner in which the trade refuse is discharged into the sewer. The largely increased volume of the sewage to be dealt

Mr. K. F. Campbell, M.Inst.C.E.

10 May, 1905.

with, and the solids present in the trade liquids give a large quantity of sludge to be disposed of.

21585. In dry weather, what is the average amount of suspended matter in the sewage, and what are the highest and lowest figures?—In dry weather the average amount of suspended solid matter is about 40·0 parts per 100,000. The maximum being 82·5 and the minimum being 23·5. (These are the figures for a dry month.)

21586. What is the physical character of these solids?—Dark grey, almost black, fine particles that settle fairly well.

21587. Can you give us average analyses of the sewage for the years 1903 and 1904 in summer and in winter?—The average analysis of sewage in summer 1903 was—

(April–September) in parts per 100,000.

Nitrogen from Ammonia free, 0·75—Oxygen absorbed 4 hours at 80° F. = 10·66.
Nitrogen from Ammonia Albuminoid—0·677; Chlorine = 13·6.

The average analysis in winter 1903 (January–March and October–December) was:—

Parts per 100,000.

Nitrogen from Ammonia free, 0·83—Oxygen absorbed 4 hours at 80° F. = 8·9.
Nitrogen from Ammonia Albuminoid 0·453—Chlorine = 10·6.

In Summer 1904 (April–September.)

Parts per 100,000.

Nitrogen from Ammonia free, 1·25—Oxygen absorbed 4 hours at 80° F. = 11·3.
Nitrogen from Ammonia Albuminoid 0·675—Chlorine = 14·4.

In Winter 1904 (Jan.-March and Oct.-Dec.).

Parts per 100,000.

Nitrogen from Ammonia free, 1·17—Oxygen absorbed 4 hours at 80° F. = 10·74.
Nitrogen from Ammonia albuminoid, 0·691—Chlorine = 12·43.

21588. Is it a "strong" sewage, and, if so, what characterises its strength?—It is not excessive in strength, but the character of the trade refuse which forms about 30 per cent. of the total volume of sewage renders its treatment difficult.

21589. Does its strength vary very much from hour to hour or on different days of the week, and, if so, do these variations affect the quality of your final effluent to a marked degree?—There are variations in strength almost every hour, due to the irregular rushes of trade liquids. During the night, on Saturday afternoons and Sundays, and during general holidays, it is of an entirely different nature to the usual week-day sewage, being in the first case of a weak domestic nature, and in the second a fairly strong manufacturing sewage. The effluent during the day does not vary much as a mixing process goes on in the tanks. The night and week-end effluents are, of course, weaker than those of week-days.

21590. How do you think "strength" of sewage as affecting purification is best expressed or measured?—(a) By the amount of nitrogenous organic matter. (b) By the amount of oxidisable organic matter as measured by the four hours' oxygen absorption. Chlorine should also be estimated to show that the sewage and the effluent are identical.

21591. Have you any information as to the bacteriological condition of your sewage in dry weather and in storm times?—No reliable information on the point at present. Investigations are in operation.

21592. Are there any chemical poisons in the sewage?—Yes, there are frequently coal tar products, aniline, nitrobenzenes, phenols, etc. The quantities vary, some days the whole works are pervaded by the characteristic odour of nitrobenzene, whilst at other times there is no trace of such an odour.

21593. Is the sewage always alkaline?—It is nearly always alkaline; at times it is acid for short periods, due to the sudden rushing of an acid liquor down the sewers.

21594. Do you find that the amounts of suspended solids are increased or diminished in times of storm; and can you give the Commission the figures at the end of each hour during a storm of some hours' duration?—Yes, and they vary as to the condition of the sewers before the storm as well as the rate of inclination to which the sewers are constructed. It would, I think, be misleading to give figures under this head.

21595. How many years ago were your sewers laid, and do you know whether they have sunk much in places so as to allow solids to accumulate?—The main intercepting sewer was constructed in 1881 to 1885. Branch sewers have been constructed at various times from that date up to the present time. There are no instances where the sewers are sunk so as to allow solids to accumulate.

21596. What is the character of the liquid part of the sewage in storm times? Perhaps you could illustrate this answer by analyses of the liquid portion of the sewage in dry weather and in storm times?—The first flush is very polluting for about an hour, after which it becomes weaker according to the length of the storm. Analyses give the oxygen absorbed of liquid portion, after settlement: (a) Dry weather, 8·94; (b) wet weather, 5·60.

21597. In what way or ways do you think the sewage which comes to the works should be dealt with in storm times? Perhaps I should amplify this question a little. The usual requirements of the Local Government Board, are, I understand, that any increase in flow up to three times the normal dry weather rate should be fully dealt with by the ordinary complete plant, and that a certain number of additional dilutions—up to a total of six—should be treated on special storm filters. Do you think these are proper requirements, or do you think they should be modified in any way? It is, I believe, often found that the storm sewage which first comes down to the works contains a largely increased amount of suspended solids, and I should like to know whether you consider that your ordinary (dry weather) plant is exposed to damage in any way—as *e.g.*, rapid choking—by having to deal with this amount of storm sewage, and whether you think it would be better to adopt some other treatment. Although the storm sewage, including the suspended solids, is a very polluting liquid, possibly the liquid portion alone is not very polluting, and this suggests that settlement of all the sewage arriving at the works in time of storms in tanks for a few hours, after, possibly, the addition of chemicals, might perhaps be a better plan of treatment than passing a portion of it through the ordinary plant, and the balance through storm filters. Would such settlement alone be sufficient for the whole of the sewage arriving at the works in times of storm?—The requirements of the Local Government Board appear to me to work satisfactorily in the majority of cases. There are instances, however, where the conditions laid down by the Board can only be adopted with considerable difficulty on the part of local authorities, for the reason that the treatment by the ordinary plant of three times the normal dry weather flow must expose the plant to a certain amount of damage, and therefore I think the Board's requirements might be modified so as to provide for the treatment of any surplus over the dry weather flow, and up to six times that volume, in sedimentation tanks, and then on storm beds specially provided for that purpose. When the storm sewage is not very polluting, it should be dealt with in the manner suggested rather than by the ordinary plant. After six times the dry weather flow the storm water could go direct into the river.

21598. What shape and size are your storm overflows?—Circular in shape, and from 2ft. 0in. to 3ft. 9in. in diameter.

21599. Would it be possible to have a standard form of overflow?—It would not be possible.

21600. Do you think that the point at which storm overflows should come into operation should depend on the configuration of the land, *e.g.*, whether it is hilly or flat, etc., and upon the character of the surface soil geologically?—The better test would be to fix storm overflows to a certain fixed volume of flow independent of the configuration or character of the ground.

21601. Should storm overflows be fixed or movable?—Fixed.

21602. Do you think the number of dilutions at which storm sewage may properly be allowed to pass

into the stream should be dependent upon the size and nature of the stream into which the storm sewage would pass? Is it possible, for example, that in some circumstances no injury to the stream would be caused by allowing overflows to come into operation when the increased flow was slight while in others this would not be the case?—This would depend entirely upon the size, nature, and location of the stream. It is quite possible that in some cases no injury to the stream would be caused by admitting storm overflows at slightly increased flows, whilst in others it would be dangerous to public health.

21603. What are your views as to the comparative cost and advantages of the separate and combined systems of sewers?—This depends entirely on the method of treatment. It is impossible to fix a general rule in such cases.

21604. Is the Huddersfield sewage settled, and, if so, how; *i.e.*, by quiescent settlement or continuous settlement; and what length of time does it stay in the tanks or take to pass through, as the case may be? Would you kindly give an average analysis of the tank liquor, including the figures for suspended solids?—Settlement by sedimentation alone has not been tried to any great extent. For a short period the septic tank was used at about twice its ordinary rate (*i.e.*, 10 hours in tank instead of 24 hours), when practically only a settling action went on. The results in this case were practically the same as in the case of septic action.

21605. Have you data to show what proportion of the suspended matter in your sewage is settled in ½-hour, 1, 2, 3, 4, 5, 6, 12, and 24 hours, if the sewage is given quiescent settlement?—I have no reliable data.

21606. What time would be necessary for you to gain a good tank liquor containing, say, no more than 6 or 8 parts of suspended solids per 100,000 from your sewage (without the addition of chemicals) by quiescent settlement and by continuous flow settlement?—Eight hours by continuous flow.

21607. Do you prefer to use settlement tanks in series or in parallel?—In parallel.

21608. In the case of continuous flow tanks, do you think there is any advantage in the employment of baffling boards or walls?—There is a slight advantage in the employment of baffling boards; they prevent the sludge from accumulating at the outlet end of the tank.

21609. How is the sludging of tanks done at your works, and what is the character of the sludge? Does any nuisance attend the operation, and, if so, is it serious? Have you means of storing sludge, or do you have to get rid of it as soon as it is removed from your tanks?—The clear liquid is run off by means of floating arms, and the sludge removed by means of sludge conduits to a receiving chamber, raised by compressed air, pressed and burnt—a most costly arrangement. We have used sludge lagoons, in which additional septic action takes place without the least nuisance attending the operation.

21610. Should the heavy (road detritus, etc.) portion of the suspended matter in sewage be removed as a first operation, or do you think it better and more economical to let everything settle in the tanks, and subsequently to screen the sludge?—Certainly, all grit should, in the first instance, be removed by the aid of detritus tanks.

21611. What is the manurial value of your sludge, and will farmers take it?—It has no manurial value, and farmers will not take it in this district.

21612. Are there any chemical poisons in it?—None.

21613. Do you find any nuisance from the treatment of sewage in settlement tanks? Have any complaints been made?—No.

21614. Have you had experience of the chemical precipitation of sewage?—Yes, for 26 years.

21615. Have you any reason to think that sewage from which the solids have been removed by the aid of chemicals is less easily purified by subsequent filtration than sewage from which the solids have been removed by settlement or by passage through septic tanks?—No; generally I have had as good an effluent from the contact beds, treating chemically precipitated sewage as from those treating septic tank effluent.

21616. Have you tried various chemicals? Can you give any comparative data on the practical value and cost of different precipitants for the preliminary treatment of sewage, stating whether you are referring to the precipitation of strong or of weak sewage?—Yes. Ferrozone used and quickly abandoned. Cost about £4 per million gallons, and gave a purification of 31 per cent., as measured by the albuminoid ammonia. Treatment with lime and copperas was successfully adopted for seven years at a cost of about 17s. 11d. per 1,000,000 gallons, and purification 54 per cent. Very satisfactory. The percentages here given are based on the workings under same conditions of sewage.

Mr. K. F. Campbell, M.Inst.C.E.

10 May 1905.

21617. What is the most effective way of adding chemicals?—In the case of lime, the most effective way is to apply it as milk of lime, and to discharge it into the sewage from five to ten minutes in advance of the copperas.

21618. What is the average analysis of the liquor from your precipitation tanks, and what length of time does the sewage remain in the tanks?—The average analysis of tank effluent from chemical precipitation and subsidence is as follows:—

	Pts. per 100,000.
Nitrogen from free and saline ammonia	1·21
Nitrogen from albuminoid ammonia	0·328
Chlorine	11·70
Oxygen absorbed in 4 hours at 80° F.	5·74
Solids in suspension	7·04

The period of settlement in the tanks is six hours.

21619. What is the character of the suspended matter in such liquor?—The solids in suspension are usually finely divided matters which are difficult to entangle in the precipitate.

21620. Do you find it necessary to add further chemicals to the sludge before it can be dealt with? If so, for what reasons, and what chemicals do you use and how are they added?—Yes; lime is used to render the liquid sludge more manageable before pressing. It causes a better separation of the solid matter. The lime is slaked and made into a cream with water; this is run into the ram along with the sludge, and the whole forced by compressed air into the presses.

21621. What is the manurial value of the sludge obtained by the chemical precipitation of the sewage at your works, and will farmers take it?—The sludge has not much manurial value, owing to the presence of a fairly large quantity of fatty matter, which forms about 20 per cent. of the dry, solid matter.

21622. Does it contain any chemical poisons?—No.

21623. Do you find any nuisance from the treatment of sewage in chemical precipitation tanks? Have any complaints been made?—No; there is no nuisance, and no complaints have been made.

21624. As regards septic tanks, how should they be shaped?—Long, rectangular.

21625. Should they be divided into sections?—If space is not available for a good length it is advisable to have tanks divided into sections in order to slacken the flow.

21626. Should they be used in series or in parallel?—In parallel.

21627. Is a scum necessary or desirable?—A scum is not necessary.

21628. Should the septic tank be closed in, and, if so, what advantages does a closed tank possess over an open one?—There is not the slightest advantage in a closed tank. There are many disadvantages, such as danger and cost.

21629. What do you consider the best arrangement for the "feed" and "draw-off"?—Delivery a few feet below the surface of the liquid, so as to minimise the disturbance of any deposit, forms the best arrangement for feed. For the draw-off, a long pipe with a slot on the under side, the effluent to pass over a lip or sill, so as to allow for aeration before discharging on to the filters.

21630. At what rate is sewage, as a matter of custom, passed through your septic tanks?—The tank deals with a volume equal to its own capacity every 24 hours.

21631. What is the most advantageous rate of flow through septic tanks, and what is the rate of flow at

Mr. K. F. Campbell, M.Inst.C.E.
10 May, 1905.

which quicker passage through the tanks becomes, in your opinion, distinctly disadvantageous? Do you think that the rate of flow should depend on the strength or character of the particular sewage which is being dealt with?—For an average sewage, 24 hours in the tank is the most advantageous. Any rate below 12 hours in the tank is disadvantageous, for the reason that complete septic action cannot be obtained under 12 hours, and by leaving the sewage in the tanks more than 24 hours does not produce any better results. Weak sewage can with advantage be passed through the tanks at a much greater rate.

21632. Is it possible to "over-septicise" a sewage, and, if so, for what reasons, and how is the "over-septicising" brought about?—Yes; the products formed by over-septicising being injurious to the nitrifying organisms in the filters. This is brought about by carrying the septic action too far.

21633. What is the amount of digestion in your septic tanks, and how do you calculate this?—About 38 per cent. of the solids deposited in the tank. This is calculated by measuring the sludge left in the tank after a known volume of sewage has been passed through, estimating the solids in the sewage and in the tank effluent during the period, and so calculating the quantity of solid matter deposited. The quantity deposited less the quantity found being the amount digested.

21634. Do you think a certain amount of sludge should be removed periodically from septic tanks, or do you prefer to work them for a considerable period without cleaning and then remove all the sludge?—I think it better to let the sludge accumulate until there is a marked increase in the suspended matter coming away with the tank effluent. Then I think the bulk of the sludge should be removed, but not the whole of it, as some should be left in to set up septic action more readily when the tank is refilled.

21635. How often would you clean out the tanks?—The time will vary with the state of the weather and other conditions, but I should say about every six months.

21636. How do you think the sludge should be taken out of the tank, and how should it be disposed of? Does any nuisance attend the operation?—The best way is to run it out by means of a sludge valve at the bottom of the tank, and dispose of it either by pressing and burning or by depositing in lagoons, the latter provided special facilities are offered for such a process. No nuisance can be caused by pressing and burning, nor have I found any to prevail by depositing the sludge in lagoons. In the latter case, much depends on the quantity of sludge to be disposed of and the locality.

21637. Do you find that the suspended solids coming away with the tank liquors tend to increase in amount towards the end of the period of working, *i.e.*, as the time approaches for removing sludge from the tank?—Yes, the suspended solids increase towards the end of the period. This is taken as an indication that the tank needs sludging.

21638. What amounts of suspended solids, stated in parts per 100,000, are contained in your septic tank liquor at the commencement of the period of working the tank, *i.e.*, just after the tank has been cleaned out, and at the end of period, *i.e.*, when the tank is thrown out of use for the purpose of cleaning out, and what is the average amount?—An eleven months trial gave the following:—(a) At commencement: suspended solids =6·6 parts per 100,000; (b) at end: suspended solids =23·3 parts per 100,000; (c) average during period =13·2 parts per 100,000.

21639. Should any portion or the whole of the sewage which arrives at the outfall works in storm times be passed through the septic tanks?—It is not advisable to pass the storm water through the septic tanks.

21640. If storm sewage is passed through a septic tank, does this cause an increase in the amount of suspended solids issuing from the tank, and, if so, can you give us figures (in parts per 100,000) showing what the increase is?—I cannot give figures, but believe the solids will remain in the tank under a certain rate of flow.

21641. May you admit storm sewage to your septic tank, to an extent which raises the ordinary level of the liquid, without serious detriment to the functions of the tank?—It would impair septic action for a time.

21642. With certain automatic gear the level of the liquid in a septic tank fluctuates. Have you made any observations for the purpose of determining whether such fluctuations disturb the proper working of the tank in any way, as *e.g.*, by causing an increased amount of suspended solids to issue from the tank?—I have no information.

21643. Do you find that septic tank liquor is more easily treated on filters than settled sewage or than precipitated sewage, assuming that in each case you have the same amount of suspended solids in your tank liquor? Kindly state what observations you have made on this point, along with what you consider the reasons for advantage or disadvantage of the one or other process?—On the assumption that in each case the suspended matter in the tank liquors are the same, septic tanks prepare the sewage better for the beds than either settlement or chemical precipitation. This is, of course, assuming that the sewage is not acid or strongly antiseptic, in which case there would be no septic action. The usually increased quantity of free ammonia indicates that some of the complex nitrogenous bodies have broken up, and present themselves in a form more favourable to oxidation than before, much of the organic matter is given off as gas, whilst the remainder seems to be more easily acted on by the aerobic bacteria than would be the case if no anaerobic action had taken place.

21644. Are the impurities in solution in sewage materially different from the impurities in solution in septic tank liquor?—Yes. The complex bodies present in sewage are reduced, there being a very much smaller albuminoid ammonia and a smaller quantity of oxygen absorbed than in settled sewage, whilst the free ammonia is higher.

21645. Have you any data on the relative value of plain septic tanks and septic tanks filled with rough stones or flints?—No.

21645*. Do you find any nuisance from the treatment of sewage in septic tanks? Have any complaints been made?—There has been no nuisance, and no complaints have been made.

21646. Do you think it desirable that the suspended solids in sewage should be removed, as far as practicable, before sewage is filtered? If so, what do you consider a practicable limit to get down to? Kindly give the figures in parts per 100,000?—Yes, it is most desirable that the suspended solids should as far as possible be removed before applying the sewage to the beds. I think 6 to 8 parts per 100,000 of suspended solids is a practicable limit to reach for a tank effluent.

21647. How do you consider that this can best be done?—The effluents from chemical precipitation tanks are most free from suspended solids. If, however, a septic tank could be so arranged that a portion of the sludge near to the outlet could frequently be removed, equally good results might be obtained.

21648. Have you any experience of any mechanical device or any special tanks for freeing liquor of suspended matter before delivering it to filters?—None of any value.

21649. What other, if any, method of dealing with tank liquor before delivering it to filters do you regard as necessary or advisable?—None.

21650. May I ask you to put before the Commission a full statement of your views as to the comparative cost and relative advantages of the various methods of settlement? I am not sure whether it would be possible for you to make this comparison on the assumption that in each case you reduce the same sewage down to the same figure for suspended solids, but if this could be done it would be useful to include a comparison on this basis. Kindly include the following methods so far as you have experience of them:—Quiescent settlement without chemicals; quiescent settlement with chemicals; continuous flow settlement without chemicals; continuous flow settlement with chemicals; septic tank treatment?—Of the two methods of settlement named, the continuous flow is the better, as this

requires little or no attention, whilst on the quiescent system the tanks must be run off and filled up from time to time. On the assumption that by each of the methods mentioned the same amount of suspended solids will be present in the tank effluent, it would be a waste of money to use chemicals at all, as precipitation only gets rid of matter in suspension. By chemical methods the process would be much quicker, so that it therefore becomes a question of initial cost, standing charges, and space. Septic tanks are, on the whole, the best arrangement. The initial outlay will, of course, be larger, but considering sludge production and subsequent purification of the tank effluent, together with the attention required, I think the annual cost will be very considerably less than with the other methods named.

21651. As regards contact beds, is it advisable to construct the whole or any part of the interior of building materials, or may you in some cases dispense with this entirely?—I think it is advisable to employ building material in the construction of contact beds if it should be considered advisable to use such beds at all.

21652. Do you find that within certain limits the depth of contact beds may vary without affecting their efficiency? If so, what limits do you think are permissible?—They should not be of a greater depth than 4 ft.

21653. What do you consider is the most convenient size for a contact bed?—About one acre.

21654. What do you find to be the best filtering materials? What is the material (which can be had in practicable quantity) that, while efficient, is in your experience the least disintegrable in a contact bed?—Good hard clinker that will not disintegrate.

21655. What size should the filtering material be, and should it be graded in the beds?—It should not be too fine, and should be graded in the beds. I should suggest for top 6 in. fine clinker ($\frac{1}{4}$ in. to $\frac{5}{8}$ in.); for middle 2 ft. 6 in. medium clinker ($\frac{1}{4}$ in. to 3 in.); bottom, 6 in. rough clinker (5 in. to 6 in.).

21656. How should the bottom of the bed be constructed?—Of concrete, with a slight fall, and underdrained with perforated pipes.

21657. Do you think it generally desirable that sewage should be subjected to some form of tank treatment before it is put on contact beds?—Yes, certainly.

21658. What periods of filling, standing full, emptying, and standing empty do you consider best in practical working for primary beds and for secondary beds?—For primary beds one hour filling, two hours standing full, one hour emptying, and four hours resting. The secondary bed at Huddersfield has generally been through a similar cycle to the primary bed, as one is fed directly from the other.

21659. How should contact beds be filled and emptied—They should be fed by means of distributing troughs so arranged as to give pretty equal applications to each section of the bed. They should be emptied by means of a valve placed at the foot of the bed.

21660. If you have had experience of automatic gear for filling and emptying contact beds, would you kindly give your views of such gear?—In my experience all the automatic gear at present on the market falls short of what is required for successful operations for filling and emptying contact beds.

Mr. K. F. Campbell, M.Inst.C.E. 10 May, 1905.

21661. What amount of tank liquor per cubic yard of filtering material can in practice be properly treated in a primary contact bed per 24 hours? If the amount varies with the quality of the tank liquor, please say by analytical figures what quality of tank liquor you are assuming, and how differences in the tank liquor affect the amount that can be properly treated?—The amount of sewage which can be treated per cubic yard of filtering material varies naturally with the strength and nature of the sewage and tank effluent. It is possible to treat much more in the early morning or during week ends and general holidays than on ordinary week-days. The amount also depends on the rate of silting up of the beds. The beds treating chemically precipitated sewage having an average of suspended solids of 7·0 parts per 100,000 have after a period of three years 31 per cent. of the original liquid capacity of the tank, whilst the bed treating septic tank effluent, with an average of 13·2 parts per 100,000 of suspended matter, has only 25 per cent of the original water capacity of the tank. From these figures, and reckoning on three fills per 24 hours, 156 gallons per cubic yard of effluent from chemical precipitation tanks and 126 gallons per cubic yard of septic tank effluent can be treated daily. Differences in tank liquor affect the amount that can be treated: (1) By reason of strength, the weaker the tank effluent the quicker the treatment; (2) by reason of suspended solids, those having more suspended matter causing the beds to silt up more rapidly than those with less. These quantities are for beds 3ft. 6in. deep.

21662. What amount of liquor from a primary bed can in practice be properly treated on each cubic yard of filtering material of a secondary bed in 24 hours?—The fine bed has a capacity which is 33 per cent. of the original water capacity of the tank, and for a bed 3ft. 6in. deep, having three fills a day, 166 gallons per cubic yard may be treated. It is, of course, possible to treat the effluent from the primary bed more rapidly on the fine bed than has been done at Huddersfield, in which case perhaps four or five fillings a day may be reckoned on.

21663. Can these quantities be increased by more frequent filling and emptying in times of storm without impairing the efficiency of the beds or the quality of the effluents?—These quantities may be increased in times of storm without impairing the efficiency of the bed. The first flush of storm sewage, which is very polluting, should not be allowed on to the beds, but afterwards, as the sewage becomes more dilute, five or six fillings a day may be given with fairly good results.

21664. Is one contact sufficient for the conversion of certain tank liquors into a satisfactory effluent?—For weak tank liquors, such as are usual in times of heavy storms, week-ends, and nights, one contact is sufficient. Tank liquors having an oxygen absorption of from two to four parts per 100,000 with one contact give effluents with from 0·5 to 1·4 parts per 100,000.

21665. At what rate or rates do primary contact beds and secondary contact beds lose their water-holding capacity?—The beds lose their capacity very rapidly at first, and then remain fairly constant for some time, the coarse bed at between 20 and 30 per cent. of original capacity of tank and the fine bed at about 33 per cent. of original capacity of tank. After the end of three years' working the capacity of the coarse bed gradually dropped from 25 per cent. to 16 per cent. of original tank capacity at the end of the fourth year. On resting the beds the capacity increases slightly, but soon falls off again. The following are the records of capacity of beds treating effluent from open septic tank.

Mr. K. F. Campbell, M.Inst.C.E.

10 May, 1905.

CAPACITY OF COARSE BED.

—	Capacity in Gallons.	Capacity as per cent. of Empty Tank.	Weeks in Operation.	Number of Fills.
Empty tank	6,739	100	—	—
August 22nd, 1900	3,987	59	Initial water capacity.	
September 24th, 1900	2,956	44	5	—
November 13th, 1900	2,730	41	12	—
January 14th, 1901	2,520	37	21	—
March 11th, 1901	2,150	32	29	—
April 15th, 1901	2,030	30	34	—
June 4th, 1901 (after 4 weeks' rest)	2,560	38	41	—
June 10th, 1901	2,220	33	42	—
June 24th, 1901	2,130	32	44	—
July 8th, 1901	2,000	30	46	—
August 19th, 1901	1,900	28	52	—
September 24th, 1901	1,820	27	57	—
October 21st, 1901	1,800	27	61	—
November 25th, 1901	1,820	27	66	—
December 16th, 1901	1,670	25	69	—
January 13th, 1902	1,770	26	73	—
February 14th, 1902 (after 2 weeks' rest)	1,950	29	77	—
March 11th, 1902	1,620	24	81	—
May 26th (after 4 weeks' rest)	2,270	34	92	—
June 10th, 1902	1,940	29	94	—
June 30th, 1902	2,140	32	97	—
July 21st, 1902	2,000	30	99	—
August 5th, 1902	1,940	29	102	—
October 6th, 1902	1,740	26	111	—
October 27th, 1902	1,750	26	114	—
December 22nd, 1902	1,610	24	122	—
January 8th, 1903 (after 2 weeks' rest)	2,050	30	124	—
January 12th, 1903	1,870	28	125	—
March 4th, 903	1,680	25	132	—
April 20th, 1903	1,620	24	135	2 weeks' rest.
June 16th, 1903	1,580	23	143	—
September 21st, 1903	1,580	23	157	—
November 9th, 1903	1,530	23	164	—
January 19th, 1904	1,430	21	174	—
April 11th, 1904	1,390	21	186	—
May 16th, 1904	1,280	19	191	—
August 29th, 1904	1,060	16	206	Rested 1 week
October 3rd, 1904	1,130	17	211	—
December 29th, 1904	1,026	16	223	Rested 3 weeks

With the exception of a short period at the commencement of the experiment and the eighteen weeks of rest the bed had been filled three times per day during six days per week.

FINE BED.

—	Capacity in Gallons.	Capacity as per cent. of Empty Tank.	Weeks in Operation.	Number of Fills.
Capacity of empty tank	6,739	100	—	—
August 22nd, 1900	3,900	59	Initial water capacity.	
February 28th, 1901	2,500	37	28	—
March 11th, 1901	2,250	33	29	—
July 9th, 1901	2,570	38	46	4 weeks' rest.
September 24th, 1901	2,340	35	57	—
October 21st, 1901	2,330	35	61	—
November 25th, 1901	2,340	35	66	—
January 13th, 1902	2,280	34	73	—
December 22nd	2,160	32	122	6 weeks' rest, 2 in February and 4 weeks in May.
March 4th, 1903	2,200	33	132	2 weeks in January, 1903.

The bed is filled directly from the primary bed, and has been treated in the same manner as regards filling and periods of rest.

A small catch-pit is placed between the two beds to keep back some of the suspended solids in the effluent from first contact.

The tank liquor is that from the open septic tank.

AVERAGE ANALYSIS.

—	Nitrogen from Free Ammonia.	Nitrogen from Abuminoid Ammonia.	Oxygen absorbed in Four Hours at 80° F.	Chlorine.
Open Septic Tank	1·91	0·499	6·16	12·10
1st Contact Effluent	0·73	0·263	3·00	—
2nd Contact Effluent	0·18	0·156	1·53	12·00

Suspended Solids in Tank Effluent = 13·1.

Suspended Solids in 1st Contact Effluent = 6·4 (mostly settled before going on to bed).

21666. Is the loss of capacity in direct proportion to the volume treated and the amount of suspended solids contained in the liquid which is put into the bed or to the fineness or coarseness of the material of the bed, or on what does it depend?—It varies directly with the quantity of sewage treated, and also with the suspended solids, but not in any fixed proportion. The fineness or coarseness of a bed will also make a difference, as in coarse beds the solid matter has more chance to get to the bottom of the bed and to be washed away with the effluent. The loss also is partly due to degradation and consolidation of the material of the bed.

21667. Can the material of a clogged bed be washed, and, if so, how can this best be done, and at what cost per cubic yard?—This arrangement can be done, and I have done it, but the cost is prohibitive, and should not be entertained.

21668. How can the capacity of contact beds be best maintained?—By keeping the suspended solids in the tank effluent as low as possible, and by having a layer of fine material on the top of the bed which can from time to time be removed and renewed. Also by selecting material for the beds which will not readily disintegrate, and by frequent resting of the bed. Even then I am not prepared to say that the processes named will be effectual.

21669. What is the average analysis of your single contact bed effluent and your double contact bed effluent?—The average analyses are as follows:—

EFFLUENT FROM SINGLE CONTACT.

(a) After Chemical Precipitation and Subsidence.

	Parts per 100,000.
Nitrogen from free and saline ammonia	0·43
Nitrogen from free albuminoid ammonia	0·14
Oxygen absorbed in four hours at 80° F.	2·06
Solids in suspension	3·43

(b) After Open Septic Tank.

	Parts per 100,000.
Nitrogen from free saline ammonia	0·73
Nitrogen from albuminoid ammonia	0.263
Oxygen absorbed in four hours	3.00
Solids in suspension	6.43

Mr. K. F. Campbell, M.Inst.C.E.

10 May, 1905.

EFFLUENT FROM DOUBLE CONTACT.

(a) After Chemical Precipitation and Subsidence.

	Parts per 100,000.
Nitrogen from free and saline ammonia	0·09
Nitrogen from albuminoid ammonia	0·083
Nitrogen from nitrates and nitrites	0·86
Chlorine	12·00
Oxygen absorbed in four hours	1·10
Suspended solids	2·11

(b) After Open Septic Tank.

	Parts per 100,000.
Nitrogen from free and saline ammonia	0·18
Nitrogen from albuminoid ammonia	0·156
Nitrogen from nitrates and nitrites	0·49
Chlorine	12·0
Oxygen absorbed in four hours	1·53
Solids in suspension	1·86

21669*. Please state the number of gallons of liquid treated daily per cubic yard of filter material in your first bed, and the number of gallons treated daily per cubic yard of filter material in the two filters?—The average quantity treated per cubic yard for the three years 1902-3-4 has been—

(a) After Chemical Precipitation.
186 gallons on coarse bed.
100 gallons for double contact.

(b) After Open Septic Tank.
105 gallons on coarse bed.
71 gallons for double contact.

21670. Do you find any chemical poisons in your final effluent?—No.

21670*. What is the average amount of suspended matter in the primary bed effluent and the secondary bed effluent? Does most of this suspended matter come out with the first flush or not?—The amount of suspended matter in

(a) Primary bed is on an average
3·4 parts per 100,000 after chemical treatment.
6·4 parts per 100,000 after open septic treatment. And in

(b) Secondary bed is
2·1 parts per 100,000 after chemical treatment.
1·86 parts per 100,000 after open septic treatment.

Most of the suspended solids come out in the first five minutes.

21671 To what extent do you find that the organic matter of the suspended solids issuing in the effluent from a contact bed is different from the organic matter of the suspended solids going on to that bed?—The solids coming out are usually non-putrescible.

21671*. Is the first flush of effluent from either set of beds ever putrescible?—From primary beds it is very probable indeed that the whole of the effluent is putrescible, except in case of very weak tank liquors. I have no information as to putrescibility of effluents from different sections of the bed. Sometimes, however, the effluent from the second contact is slightly putrescible, and this may be due to the first flush being putrescible.

21672. Do you find that by increasing the number of fillings in storm times or other times the amount of suspended solids is increased?—I have no information on that point.

21673. May contact beds in times of storm be used as streaming filters without detriment to their customary efficiency, and, if so, do you think there are advantages in so working them?—Not unless they are constructed of coarse materials.

21674. What was the cost of your contact bed installation per acre, and how much liquid do you treat per acre per 24 hours in ordinary times and in storm times?—The cost of the contact beds per acre was £1,700. The area of contact beds required to treat 1,000,000 gallons in ordinary times is 2·20 acres. The area required to treat 1,000,000 gallons in times of storm is one acre. This is on the basis of double contact with beds 3ft. 6in. deep.

21675. Have you made any experiments which throw light on the action of contact beds when full and when resting?—No.

21676. Have you made a study of the conditions of aeration of contact beds, and, if so, with what results?—I have made experiments without satisfactory results.

21677. Do you find any nuisance from the treatment of sewage on contact beds? Have any complaints been made?—No.

21678. As regards continuous or percolating filters, what do you find are the best filtering materials, and what size should the material be?—A good hard clinker which will expose a good filtering surface, and which will not disintegrate. The bed should be fairly coarse, the material used being rejected by a 1½-inch mesh.

21679. What depth should a percolating bed be to obtain a good effluent?—The experimental bed at Huddersfield is 7 ft. deep and gives usually about 90 per cent. purification.

21680. Do you think it generally desirable that sewage should be subjected to some form of tank treatment before it is put on percolating filters?—Yes.

21681. Is the material better disposed in the form of two beds, to be fed in succession with the same liquid, or in one dep bed?—One deep bed of an acre in extent is required for large works.

21682. How should percolating filters be fed?—By some form of distributor which will spray the tank effluent evenly over every unit of area of the bed. This is a matter to which I have given a great amount of attention, and I have patented a spreader which provides for an equal distribution of the sewage all over the bed during all conditions of weather. The distributor covers one acre of filter bed.

21683. Should the feed be intermittent or continuous?—The spreader provides the rest required in its revolving action.

21684. What is the best form of distribution, and what are the conditions which have to be fulfilled by a perfect distributor?—The form depends on the shape and size of the filter. A good distributor should fulfil the following conditions:—

1. Every square yard of the bed should receive exactly the same dose of liquid in the same interval of time.
2. The liquid should be sprayed on to the bed in small jets or as a fine rain.
3. There should be no small holes to get easily clogged up.
4. There should be no complicated mechanism to get out of order.
5. They should work as well in high winds or frosty weather as in calm and warm weather.
6. No automatic arrangement possible except for small areas, and even then distributors now in use are subject more or less to weather conditions.

21685. Do you think it best to put on the filter a fairly constant amount of liquid, or do you consider that the amount can be increased in times of storm without impairing the efficiency of the filter or the quality of the effluent?—The amount may be increased in times of storm without impairing the action of the bed or quality of the effluent. In fact, the increased quantity will tend to flush the bed out and remove any solid matter that may have accumulated.

21686. Is there any practical advantage in artificially heating the liquid which is being treated upon percolating filters?—No.

21687. Have you had any experience to show whether open sides are an advantage to a percolating filter?—Yes, open sides are essential.

21688. Have you made any study of the conditions of aeration of percolating filters?—No.

21689. What do you consider is the most convenient superficial area for a percolating filter?—One acre.

21690. Do you think it desirable that the bottom of a percolating filter be raised from the ground?—Yes, to allow the effluent to get away rapidly and to ensure good aeration.

21691. Do percolating beds, in your experience, choke?—Properly constructed, they do not choke.

21692. Of what nature are the suspended solids in the filter effluent? How much is organic matter, and are they putrescible apart from the liquid portion of the effluent?—The solids are brown earthy matter, and easily settle. About 55 per cent. is organic matter (that is of dried solids). They are not putrescible.

21693. To what extent do you find that the organic matter of the suspended solids issuing in the effluent from a percolating filter is different from the organic matter of the suspended solids going to that filter?—The solids are more of a granular nature and are non-putrescent.

21694. Have you any experience of, or any suggestions to make on, the settlement or other separation of the suspended solids issuing from a percolating filter, and to what minimum figure do you think such settlement or other final treatment can be carried as a practical measure?—Simple settlement will remove the bulk of the solids in suspension, and minimum figure to which such settlement can be carried as a practical measure would be about 3·0 parts per 100,000.

21695. Do you find that the suspended solids in your filter effluent vary much in amount from time to time, and, if so, can you explain the causes of such variation?—The solids are always partly settled before delivery of the effluent, owing to the construction of the tank in which the filter is placed. Therefore suspended solids are not estimated.

21696. What was the cost of your percolating bed installation per acre, and how much liquid do you treat per acre per 24 hours at ordinary times and in storm times? Please give the depth of the filter and an average analysis of the liquid which you put on and an average analysis of the effluent when working at the ordinary rate and when working at a greater rate in storm times. In each case I should like you to give the figures for suspended solids if you have them?—The cost was £2,500 per acre. In ordinary times the filter treats 1·50 million gallons per acre per 24 hours. In storm times the sewage is passed more quickly through the tank and treated continuously during 24 hours at the rate of 1·88 million gallons per acre per day. The depth of the filter is 7 ft. Average analysis (after settlement of suspended solids) in parts per 100,000:—

—	In Ordinary Weather.	In Storm Times.
Nitrogen from Free and Saline Ammonia	0·23	0·05
Nitrogen from Albuminoid Ammonia	0·090	0·049
Nitrogen from Nitrates and Nitrites	1·03	—
Chlorine	11·90	10·70
Oxygen Absorbed in 4 hours	1·29	1·00

21697. Have you made any experiments which throw light on the action of percolating filters with regard to the oxidation of the ammoniacal and organic matter in solution and the organic matter in suspension?—No.

21698. Have you evidence to show that ammonium salts and organic substances in solution, not of a colloidal nature, pass rapidly through a percolating filter, or that they are absorbed by the filtering material or by growths on that material, so that their passage through the filter is a very gradual one?—No.

21699. Have you observed the effects of changes of atmospheric temperature on the working of a percolating filter?—It works equally well in hot or cold weather.

21700. Have you found any trouble from vegetable growths in percolating filters?—No.

21701. Do you find any nuisance from the treatment of sewage on percolating filters? Have any complaints been made?—No.

21702. Would you kindly compare the cost (initial expenditure and annual cost of upkeep and working) and relative advantages of percolating filters and contact beds. Do you consider that one form is best for some kinds of sewage, and the other form for other kinds of sewage?—With regard to initial cost, contact beds require a much bigger area of land, and they also usually require retaining walls, whereas percolating beds have a bigger depth and a much less superficial area; they require practically no retaining walls, large pieces of clinker answering the purpose quite well, so that the original installation would be much more costly if contact beds were used. On the other hand, the sewage can be applied to a contact bed without any special form of distributor, whilst with percolating beds it is essential that some arrangement should be provided for spreading the sewage or tank effluent uniformly over the bed. With regard to cost of upkeep, percolating beds have again the advantage provided that a good form of distributor is used. Beyond some little time for cleaning and repairing the sprinkler no attention is needed, whereas contact beds have to be filled and emptied at regular intervals, and in large installations this can only satisfactorily be done by hand. In addition, the beds require frequent raking or digging over to be able to maintain anything approaching a working capacity. The relative advantages of percolating beds and of contact beds are—

(1) Percolating beds do not require so large an area as contact beds.

(2) Percolating beds do not require retaining walls, which are costly.

(3) Percolating beds do not lose their capacity.

(4) Percolating beds produce an effluent which is usually richer in dissolved oxygen and in oxidised nitrogen than contact beds, and have therefore a bigger reserve supply of oxygen.

(5) The irreducible matter comes away with the effluent in percolating beds, whilst in contact beds it is retained to the detriment of working capacity of the bed.

(6) Contact beds in my experience are not adapted under any circumstances for large sewage schemes.

21703. Do you find that the chance of nuisance is any greater with one form of filter than with another? Does the risk of nuisance depend on the kind of sewage which is being treated or on the nature of the preliminary treatment to which the sewage has been subjected? The question of nuisance is important, and I should be glad if you would state your views fully on these points?—No, both forms of filter are free from smell. Probably with a purely domestic sewage there might be some nuisance caused by the treatment in open septic tanks, but with the sewage of large manufacturing towns, which is weak in domestic refuse and strong in trade refuse, no nuisance is experienced.

21703*. Have you made any comparative observations which show how many gallons per cubic yard per 24 hours of your tank liquor or tank liquors could be satisfactorily purified on a percolating filter, and how many gallons per cubic yard on contact beds? If so, would you kindly state the results, at the same time telling us in precise terms what was the composition of your tank liquor or tank liquors, and what you are considering to be a satisfactory effluent?—Comparisons of the amount of liquid from the open septic tank that could be satisfactorily treated per cubic yard of filtering material show that—

(a) By trickling bed, 132 gallons per cubic yard can be satisfactorily treated.

Mr. K. F. Campbell, M.Inst.C.E.

10 May, 1905.

(b) By double contact, 72 gallons per cubic yard may be satisfactorily treated (*i.e.*, taking water capacity of coarse bed as 25 per cent. and of fine bed as 33 per cent. of original capacity of empty tank). The composition of the tank liquor is as follows:—

Open Septic Tank.

	Parts per 100,000
Nitrogen from free and saline ammonia	1·91
Nitrogen from albuminoid ammonia	0·499
Chlorine	12·10
Oxygen absorbed in four hours	6·16

The effluent is satisfactory by reason of its non-putrescibility.

21704. Could you express an opinion as to how the number of gallons would vary with variations in the strength of your tank liquor, and on what figure or figures you would rely for defining the "strength" of your tank liquor?—With weak tank liquors I can treat probably half as much again. I should rely on the albuminoid nitrogen and oxygen absorbed figures for defining the strength of the tank liquor.

21705. Have you had any experience of storm water filters?—This is being made the subject of special inquiry at present, but I am unable to state definitely the results.

21706. Do you consider storm water filters lose any of their efficiency by being used intermittently at long intervals?—Yes, it is best to apply weak night sewage at fixed periods.

21706*. Have you any practical suggestions to make for disposing of sludges?—I would suggest that the different kinds should be disposed of as follows:—

(a) Sewage screenings: Tipping or burning.
(b) Material from detritus tank: Tipping.
(c) Sludge from precipitation tanks: Depositing in lagoons.
(d) Sludge from septic tanks: Depositing in lagoons.
(e) Sludge from settlement tanks: Depositing in lagoons.
(f) If the sludge has any manurial value it can be dried in heated cylinders and the moisture thus reduced to 15 per cent., ground in a mill, and sold as manure.

This is the greatest difficulty to contend with in the matter of sewage purification. The methods I have adopted are as follows:—

(1) Deposition on land in specially-prepared sludge lagoons.
(2) Pressing and tipping sludge cake.
(3) Pressing and burning sludge cake.

The pressing and tipping causes in summer time slight smell, due probably to the action of the lime used for pressing liberating gases such as ammonia. No nuisance has been experienced from the other methods. The cost of pressing and burning is, however, considerable.

21707. What, in your opinion, constitutes a good effluent?—One that will remain sweet in the incubator for a week in the absence of air.

21708. Do you consider that the type of effluent from a contact bed is superior or inferior to the type of effluent from a percolating filter?—I find the type of effluent from a contact bed is inferior to the type of effluent from a percolating bed. Nitrification is more active in the percolating bed, and there is also better aeration. So that the effluent has a better reserve supply of oxygen than one from a contact bed.

21709. What test or tests do you chiefly rely upon in judging of the quality of an effluent, and for what reasons?—I rely upon the following:—

(1) Incubator test.
(2) Oxidised nitrogen.
(3) Albuminoid nitrogen.
(4) Oxygen absorbed.

The incubator test, I think, is the best test of the quality of an effluent. If a sample will stand in the absence of air for some days at a temperature of a hot summer's day, then it is quite fit to be turned into any watercourse, even if the volume of the effluent exceeds that of the water. (I am referring here to non-potable streams.) The oxidised nitrogen is a very good test of the efficiency of the working of a bed, and also a measure of a reserve supply of oxygen. The albuminoid nitrogen is a measure of matter which is detrimental to the quality of an effluent. The oxygen absorbed is also a measure of matter which is often detrimental, and will indicate to some extent how the effluent will rob the stream of its available oxygen.

21710. Have you tried the "aeration" test, *i.e.*, the rate at which dissolved oxygen is taken up by an effluent?—A few tests have been made.

21711. Is one standard for all effluents passing into non-potable streams possible and desirable, and, if so, what should it be?—Yes, one standard, but not a chemical one, is possible and also desirable, and it should be one that can be attained equally well by large towns with strong sewages and trade waste as by small villages. The following would appear to meet the case. The effluent should be such that a sample of it will keep without putrescing for some days at a temperature of 80 deg. F. in a tightly stoppered bottle. This is a standard that is easily attained and is equally fair to towns and villages. It does not depend on the absence of more than a certain definite quantity of nitrogenous or oxidisable matter. The ideal of sewage purification should be to produce an effluent that will not putresce; and not the production of an effluent that is poor in a certain class of chemical compounds. A manufacturing effluent often contains matters which according to chemical standards would be classed as unsatisfactory or bad, whereas they are non-putrescent and perfectly harmless. The effluent from the Huddersfield percolating bed has at times had an oxygen absorbed of over 2·0 parts per 100,000, or at others an albuminoid nitrogen of ·12, or even more, and yet remained perfectly sweet in the incubator for seven days at 80 deg. F. The oxygen absorbed is chiefly due to dye liquors, which are oxidisable but are not putrescent, and which are generally present in small quantities in the effluent.

21712. Supposing a general standard to be impracticable, how should a plurality or series of standards be formulated? What amount of suspended matter would you allow in an effluent?—If a general standard be considered impracticable then local standards should be made, in the fixing of which should be taken into account:

1. The character of the stream receiving the effluent.
2. The nature of the sewage and the difficulty of its treatment.

It is not advisable to allow more than five parts per 100,000 of suspended solids. This is a standard which can be easily attained, and an increased quantity would be detrimental to the stream.

21713. What is your experience of the effect of storm water upon filters of various sorts?—I have had experience of the effect of storm water, and from what has been done it is found that generally after the first flush in times of storm the sewage can be treated more rapidly on either contact or percolating beds without any serious detrimental action on the beds.

21714. How far do you consider it advisable for a sewage installation to be worked automatically?—It is inadvisable in the case of large installations for the whole works to be dependent on automatic contrivances as these easily get out of order, and cannot at best be depended on. The sewage treatment should be carefully controlled according to results. This can only be attained by careful watching and the application of frequent tests.

21715. Have you made any systematic observations as to the effects of discharging effluents into streams?—No.

21716. Could you make a short statement setting forth the values you attach to the different chemical tests in use for determining the qualities or conditions of sewages and effluents, and giving your reasons?—The values of chemical tests vary with local conditions. As a general rule the chlorine figure will give a good guide to the strength of the sewage although this depends largely on local conditions, such as chlorine in water supply, population, system of sewerage, and proportion of domestic or trade sewage. The albuminoid nitrogen and oxygen absorbed give a fairly good indication of the substances which have to be got rid of. The two tests should, I think, be done side by side, and a comparison made. The samples should be analysed when fairly fresh, to make the results of any value, as

the putrefactive changes which go on in a bottle of sewage will break down complex matters and give simpler forms.

Of the tests which are applied to effluents, I attach most value to the incubation test for reasons already stated. Next in importance is oxidised nitrogen, as this tells immediately if the bed is working efficiently. The oxygen absorbed in four hours along with the three minutes test gives a valuable indication of how the oxidation is proceeding, and how the effluent will rob a stream of its oxygen. The albuminoid nitrogen also is a good test of purity of an effluent. The tests should be all made and compared as an effluent cannot be condemned or otherwise on any one test, except the putrescibility as measured by the three minutes oxygen absorption before and after incubation.

21716*. What are your views with regard to the quantitative determination of the "strength" of a sewage, tank liquor, etc.?—The strength of a sewage or tank effluent would, I believe, be best determined by:

Albuminoid nitrogen.
Oxygen absorbed.
Solids in suspension.
Chlorine.

The first three showing strength in matters to be disposed of, and the latter the variations in strength in different weathers. This varies, of course, with local conditions, but should be fairly constant for any one sewage.

21717. Is there any other point upon which you would like to speak at this stage?—If I may express an opinion, I would like to add that the time has now arrived for legislation dealing with the pollution of rivers by one general Act, applicable to the whole country, and the creation of a central governing authority with the necessary scientific officers for administering the Act, holding enquiries and affording equal justice to all concerned, and thus avoiding the difficulties and differences of opinion which inevitably arise between local authorities and the Divisional Boards as now constituted.

21717*. On Question 21580 it struck me that the proportion that goes over the storm overflow in comparison with what goes through your regular works is very large. Do you give the figures with confidence?—I give them from actual facts.

21718. Does it not strike you that a very large quantity goes over your storm overflow?—Yes, a very large quantity goes over, but that is due to the rapidity or the suddenness with which very large volumes come down.

21719. Are the figures you give in Question 21596 under (a) and (b) parts per 100,000?—Yes.

21720. And are they ascertained by the four hours' test?—Yes.

21721. Then on Question 21597 you say that after six times the dry weather flow the storm water can go direct into the river. Have you any particular reason for selecting the figure 6?—My reason for selecting the figure 6 is that after a number of experiments during floods I found that it would not be safe to admit into the river any quantity—taking the average for an extended period—below six times the flow.

21722. (*Colonel Harding.*) You say that your experiments led you to think that less than six times dilution would not be safe. Are we to gather that you think that above six dilutions it is safe to turn into the river?—There may be cases when it would be safe to do so, but as a general rule I find it is not so.

21723. Your objection to dealing with more than six times the flow is that it is unnecessary to deal with it, not that it is impracticable?—Certainly.

21724. (*Chairman.*) On Question 21603 you say it depends entirely on the method of treatment, whether you favour the separate or combined systems of sewerage Can you tell us with what methods of treatment you would favour one and with what the other?—For instance, dealing with the sewage chemically, if you have a combined system, of course, you will have a much larger volume to deal with, and it becomes a very expensive process. If, on the other hand, you are not dealing with the question by chemical precipitation, it would not be such a serious question.

21725. In answer to Question 21632 you say that the products formed by over-septicising are injurious to the nitrifying organisms in the filters. Have you ascertained that by actual experience?—I have.

21726. Then, on Question 21633, can you tell us how you measure the quantity of sludge left in the tank? In what way do you contrive to measure it—it is rather a difficult thing to do?—The way the sludge is measured is this. When the tank effluent is drawn off we ascertain by measurement what is the quantity of sludge left, and in order to verify it from the formulæ dealing with it I have actually weighed a cubic foot of sludge so as to ascertain in fact how it can be measured and how it agrees with other methods applied for arriving at the quantity of sludge produced.

21727. (*Sir William Ramsay.*) Was the cubic foot of sludge dried up as well?—No, it was not dried up; it was just taken up to be pressed.

21728. You ascertained the amount of water in it by experiment?—Yes.

21729. (*Colonel Harding.*) But the sludge at the bottom of the tank would be very much denser than the sludge in the upper part of the accumulation?—Yes.

21730. How do you ascertain the mean between the lower and the upper strata?—There might have been between 2ft. and 3ft. of sludge in the tank; I would at once take a cubic foot or a cubic yard, and take the average of the sludge, so as to get the same intensity all over the cubic foot or cubic yard, as the case might be.

21731. Did you take samples of the top, middle and bottom, and mix them together and take the average?—Yes.

21732. You are quite aware that there would be a very great difference?—Yes.

21733. Probably 95 per cent. of water at the top and 80 per cent. at the bottom?—Yes. I do not know of any method you can employ, except to do it in the way I have mentioned.

21734. The results you have obtained depend entirely on the careful way in which this work was carried out?—Yes. I have had the sludge mixed and the quantities ascertained under my own supervision on several occasions, and the variations were so very slight that I came to the conclusion that the results were perfectly accurate.

21735. (*Sir William Ramsay.*) I suppose that 38 per cent. means that that amount of solids was removed by the septic tank process?—Yes.

21736. (*Chairman.*) May I ask on what observations you found your answer to Question 21641, in which you say that it would impair septic action for a time?—That has been obtained by taking analyses of the sewage in the septic tank during periods of sudden storms. It has been found that with rushes of storm waters coming into the septic tank it did not perform its function so satisfactorily as if it was working under ordinary conditions.

21737. In your answer to Question 21643 you speak from actual experience and observation, I suppose?—I do.

21738. (*Sir William Ramsay.*) Have you a set of analyses published, illustrating the last sentence in your answer to Question 21643?—Yes, they are in the reports which I am putting in. (*See* Appendix: page 185).

21739. (*Chairman.*) In answer to Question 21646 you say that you think that from 6 to 8 parts per 100,000 of suspended solids is a practicable limit to reach for a tank effluent. I suppose you say that after fully considering the matter?—Yes.

21740. Of course, it is a low figure?—Yes.

21741. But you deliberately say that?—I do.

21742. Would that be by cleaning out the tank often or not?—I find that, so far as my experiments go, I can obtain this result if I clean the tank out four times a year.

21743. On Question 21667 it rather surprised me that you should say so positively that the cost of washing would be prohibitive. Can you tell us at all what the cost would be?—In my case, when carrying out the operations here referred to, it came to between £5 and £6 per million gallons.

21744. (*Sir William Ramsay.*) The washing?—Yes.

21745. (*Chairman.*) Can you calculate what the cost was per cubic yard?—I could, and will submit the figures afterwards.

21746. (*Colonel Harding.*) The point we want to get at is whether it is or is not a practicable thing to wash out the material of the contact beds. I think you ex-

Mr. K. F. Campbell, M.Inst.C.E.

10 May, 1905.

press a strong opinion that it is not practicable financially to do so, and you said something about the cost being so much per million gallons?—Yes.

21747. I do not quite appreciate what that means. What we want to know is what is the cost of washing the material of these beds. That surely must be given at so much per cubic yard?—That can be given, but I could not give it without going into the figures. In my case we deal with the cost per million gallons filtered, not per cubic yard.

21748. What has the flow to do with this particular point?—If you have a double contact, and you purify so much sewage upon a given area of double contact, you will arrive at the cost of the purification per million gallons.

21749. I think I see what you mean now. You mean it is the annual cost reckoned per million gallons?—Certainly.

21750. But in order to reach that have you not to find out what it is per cubic yard?—Yes; I could give that figure, but not off-hand; I have it.

21751. You are unable to give it at present?—I could not give it authoritatively at present. I deal with it per million gallons in all my reports. But it is in my opinion impracticable to carry out the process on a large scale—you cannot do it.

21752. It has been suggested to us by certain witnesses that the cost might be brought down to from 1s. to 2s. per cubic yard. You do not agree with that?—I have heard that for years, but my experience is that it is impossible to bring it down to the figure named and at the same time maintain the total capacity of your beds.

21753. (*Chairman.*) Passing on to Question 21669, comparing the effluent from the double contact, the effluent from the first process was rather better than the effluent from the second. Can you tell us at all how the cost of the two processes compares?—You mean the working cost?

21754. Yes?—In the case of the one there is very little. Take the septic tank, for instance. I reckon it makes a difference of about 30s. per million gallons treated—from 27s. 6d. to 30s.

21755. Then on Question 21670* do you see any reason why the figures should be so curiously inverted? In (a) you say that you get 3·4 parts per 100,000 after chemical treatment, and 6·4 parts per 100,000 after open septic treatment. But in (b) the figures are reversed; there are 2·1 parts per 100,000 after chemical treatment, and only 1·86 parts per 100,000 after open septic treatment?—Yes, it is a curious coincidence. These are the facts as I found them.

21756. They are the facts, but you have no explanation of them?—The explanation is due to the fact that in septic treatment the effluent from the coarse bed is partially settled by passing through a catch-pit before flowing on to the second bed, whereas in chemical treatment as at present arranged such is not the case.

21757. In answer to Question 21687 you say that open sides are essential to a percolating filter. That is a very positive statement; how do you support it?—I have tried both, and found better results from the open.

21758. Then in reply to Question 21691, again about the percolating beds, you say that, properly constructed, they do not choke. From how long experience can you speak?—About 3½ years.

21759. And have you had one percolating bed going the whole of that time?—I have.

21760. And it has not choked?—No.

21761. Or shown any signs of choking?—None whatever.

21762. (*Colonel Harding.*) How close is the material?—It ranges from 6in. to about ¾ of an inch.

21763. From 6in. to about ¾ of an inch?—Yes.

21764. Do you mean the big on the top and the ¾in. in the body?—I have 2in. of ¾in. material on the top.

21765. Where does the 6in. come in?—From the middle downwards.

21766. Graded material?—Yes.

21767. Some of it is as small as ¾in.?—On the surface it is as small as ¾in.

21768. How much?—All over the surface.

21769. But how deep?—About 2in.

21770. A mere surface covering?—Yes.

21771. What is the bulk of the filter composed of?—3in., 4in., and 6in.

21772. Then we may take it that it is a very coarse filter?—It is certainly what you would term a really coarse filter.

21773. (*Chairman.*) Is it in constant working?—Yes, to-day.

21774. And it has been in constant working for 3½ years?—It has.

21775. (*Sir William Ramsay.*) Does not the surface require frequent attention?—No.

21776. Does it not get clogged?—No; I have not touched the surface. I have given strict instructions that it is not to be touched at all unless my attention is called to it, and from the day I put down the filter to the present time it has not been touched. I am bound to say that when I started with the percolating filter I was very much averse to it, but I am now of a different mind. So far as I know from experiments that is the best filter of the present day.

21777. (*Chairman.*) Have you had many analyses made of the filtrates?—Yes, daily.

21778. And you find them good?—Yes.

21779. And you consider that the filter does its work thoroughly?—I do, most certainly. In proof of that I may say that I have advised the Corporation to put down 19 acres of this very same filter in their new scheme, and I would not have done so were I not assured of its success.

21780. (*Colonel Harding.*) We have put to you some important questions in regard to storm waters, and are naturally interested by the answers you have given us. But the opinions that you have expressed are based, I suppose, rather upon what you think should be done than upon what you actually have done at Huddersfield. I may take it, as you have not yet got your works in operation for treating your dry weather flow, that you are certainly not treating four or six dilutions?—No, I am not treating the whole; you are quite right in your observation.

21781. You have said that you think it is undesirable that storm water should be treated through the same plant as the dry weather flow, and that it is better to have a separate plant for storm waters. The impurities in storm water—are they not mainly due to suspended matter?—Yes.

21782. And I think you express the opinion that the settlement of such suspended matter might be improved by special treatment?—Yes.

21783. In any case, if further treatment were required it could be done on a percolating filter?—Yes.

21784. At probably a high rate of flow?—Yes, that is so.

21785. In regard to the sludge which you produced, you say that it has no manurial value and that the farmers will not take it?—Yes.

21786. Are you alluding to septic tank sludge or precipitated?—To both.

21787. You produce a large quantity; what do you do with it?—I burn it, and I put portions on to sludge lagoons. One half is burnt, and the other is put on sludge lagoons, allowed to dry, and then covered over with material, when it gets a hard substance—with earth and other materials.

21788. But before you can burn the sludge you must largely reduce the water in it—probably by pressing?—Yes, I press it.

21789. You press part of the sludge?—I do.

21790. And you burn the cake?—Yes.

21791. Do you do that on a large scale?—Yes.

21792. How much cake do you burn, say, per day?—From 15 to 25 tons a day.

21793. I shall be greatly interested to know whether the burning of the sludge cake causes any nuisance?—None whatever in properly constructed furnaces.

21794. Do you utilise the heat?—Yes.

21795. You do not utilise any of the gases produced by the combustion of the cake?—No.

21796. Has there been any suggestion of making gas from the sludge?—Yes.

21797. But you do not think it practicable?—Certainly not.

21798. Part of your production of sludge you burn, and the remainder, you say, you dry in lagoons and then cover up? But surely that cannot go on for ever. You will reach a time when your available site for such a purpose is all used up, and you will have to burn the whole of it or find some other means of disposing of it?—Yes, in the distant future.

21799. What do you propose to do?—To burn the whole.

21800. In your opinion the burning of cake is a practicable thing?—Certainly.

21801. That is your opinion based upon experiments?—Yes.

21802. You think it is practicable in regard to the cost and also as not causing nuisance?—It does not cause nuisance. Of course, the cost is somewhat heavy, but it is quite practicable to carry out.

21803. Passing on to the septic tanks, your present opinion is that it is well to allow the septic tanks to accumulate sludge up to a certain point and then to empty them. In theory, would it not be desirable to maintain the capacity by the frequent removal of some small portion of the sludge so as not to cause any large accumulation?—I do not think so.

21804. In your answer to Question 21638 you say that your septic tank at the beginning had an effluent which contained only 6·6 parts per 100,000 of suspended matter, whereas later on, when the sludge had accumulated, the 6·6 had risen to 23·3 parts per 100,000 of suspended matter in the effluent?—May I refer again to the question.

21805. In answer to 21638?—Yes.

21806. You say there that as the tank got older and the accumulations rose the amount of suspended matter in the effluent rose also very considerably?—Yes, it does rise.

21807. In other parts of your evidence you have expressed the opinion that it is highly desirable that suspended matter should be as far as possible removed from the effluent going on to the filters; therefore I gather that you must think it a disadvantage that the septic tank should reach this condition which yields so much suspended matter in the effluent?—But in the case of a percolating filter it has not the effect upon it that it would have upon a double contact.

21808. You think that a percolating filter will bear more suspended matter upon it than contact beds?—Certainly; it will wash away through the percolating filter, and it can be intercepted by settlement afterwards.

21809. You do not care very much, therefore, what quantity of suspended matter goes on?—I do, because I consider that even the effluent leaving a percolating filter should be submitted to a certain process of settlement before it goes into the river.

21809*. You appreciate that it would be very important even with percolating filters to keep out suspended matter from the effluent if it is practicable to do so?—Certainly.

21810. Therefore if a septic tank at first passes only 6 parts per 100,000 with its effluent and later on 23, it does appear in the abstract that it is desirable to maintain the capacity so as to prevent that important increase?—Yes, if you attach much importance to the suspended matter. Suspended matter may be quite harmless from a polluting point of view.

21811. Do not you attach much importance to it?—It is of some importance in most cases.

21812. Is it at all practicable—I think you are an engineer—to withdraw daily a small quantity of sludge from a septic tank?—It is quite possible from an engineering point of view to do it, but not advisable.

21813. If it be possible to do it would it not be desirable, so as to maintain the capacity of the septic tank and to get in the effluent from the septic tank a fairly constant quantity of suspended matter?—The only thing is that the septic tank gives slightly better results after it has been in action for a considerable time than it does when it is freshly put into operation.

21814. Obviously, when it has matured, it does better than when it is newly started?—Yes.

21815. But this better result is due to the maturing, and not to the accumulation, surely?—To the maturing, but still the accumulation helps to mature. I am certain it does.

21816. But you do not suggest that the septic tank gives better results because a large quantity of material has accumulated in it?—If you look at the analyses you will find that the best results are obtained after the septic tank has been in operation for a month or for two or three months.

21817-18. What do you mean by the best results?—The best results from the point of view of purification of the effluent as it leaves the septic tank. You get a better effluent after the tank has been in operation for some considerable time than you will get within the first week, fortnight, or month after it has started.

21819. But at the end of the period you say that you got 23 parts per 100,000 of suspended matter in the effluent?—Yes.

21820. You do not suggest that that is a better effluent than one containing six parts, do you?—No, it is not better, and so far as the quantity of suspended matter is measured, the septic action is better; the tank produces a better septic action.

21821. When the tank has matured you get better septic action; when it has only just started you get none. The important point I want to get at is whether it would not be best to maintain a constant quantity of deposit in a septic tank rather than allow it to grow many feet deep?—I quite agree with that.

21822. You agree?—I do, certainly.

21823. You think it quite possible to keep on withdrawing sludge from the septic tank?—Yes. I understood that you wanted the tank always clean.

21824. Always empty?—Yes.

21825. Oh, no?—I agree. That is a different thing altogether.

21826. You say that it is possible with a septic tank to reduce the suspended matter in the effluent under proper conditions to as low as 8 or 9 parts per 100,000?—Yes.

21827. And your way is that near the outlet you shall keep the tank fairly clear from sludge?—Yes.

21828. Would not that work in with what I have been suggesting?—Yes.

21829. Any way, you think that the point is of some importance?—It is indeed.

21830. Have you tried any experiments to obtain that?—Yes.

21831. Could you tell us what they were?—With one of the tanks—a precipitation tank—which I have at the present time the course which you suggest has been followed throughout by drawing off the liquid sludge after it got a certain volume, leaving only a small quantity of sludge at the bottom.

21832. What was the result?—The result, as I have shown here, was a higher degree of purification, with less solids in the tank's effluent.

21833. You express a very strong opinion that contact beds should not be deeper than 4ft. Upon what do you base that opinion. I am referring to your answer to Question 21652, where you say "they should not be of a greater depth than 4ft." What leads you to say that?—In 1898 I started with a series of contact beds 3ft. deep. I increased the height to 3ft. 6in., and I went up to 4ft. and to 4ft. 6in., but I found that at 4ft. 6in. the results were not as satisfactory as they were at 4ft. The experiments went on from time to time over 12 months until I fixed on 4ft. as the maximum height to which a contact bed with our sewage should be constructed. With a depth of 4ft. we get better results than from the 4ft. 6in.

21834. You found a positive deterioration by adding an additional 6 inches?—I did slightly.

21835. Were these experiments carried out with the care necessary to enable you with confidence to make that assertion?—Yes; in fact, they were carried out for a purpose, and the purpose was that in the new scheme which I have designed for Huddersfield I thought contact beds would be the best system to adopt, and I was naturally anxious to get a bed that would give the greatest cubical capacity so as to avoid purchasing additional land.

21836. If you have at present working a 4ft. bed which is giving good results, and if you add 6in. on the top, do you say it is going to make the results

Mr. K. F. Campbell, M.Inst.C.E.

10 May, 1905.

worse?—Well, put on another foot. Six inches is so very little, but if I put on another foot I get a worse result. That is my experience.

21837. But you have not tried 5ft.?—I have tried up to 4ft. 6in., and found that anything over 4ft. did not improve the efficiency of the bed.

21838. You think that if you have a 4ft. contact bed in good working order and you add a foot to it it will injure the results?—The results are less satisfactory whatever height you go above 4ft.

21839. You speak about the washing of contact beds when they get choked by accumulations being quite prohibitive in cost?—Yes.

21840. Have you really tried on a fairly large scale to wash a contact bed?—I have.

21841. And with proper appliances?—Yes.

21842. And you have no doubt that, situated as you are at Huddersfield, it was quite impracticable?—That is so.

21843. What is the alternative. I take it that a contact bed is bound to sludge up at some time?—Undoubtedly.

21844. Is the only possible alternative to renew the material?—To renew the material, or to turn it over and wash it. I do not know of any other system.

21845. But you said that washing is impracticable?—Yes, from a financial point of view.

21846. Then the only alternative is the renewal of the material?—Yes.

21847. Is that also impracticable financially?—I think it is financially.

21848. Then your opinion is that contact beds themselves are impracticable?—On any large scale I hold very strongly that they are.

21849. You do not think that the contact bed system is one that should be used at all?—I do not think it should be used at all, except perhaps in very small installations, where the cost of renewals would only be trifling.

21850. They are bound to sludge at some time, and it is impracticable financially to renew the material or to wash it?—Yes.

21851. You are in favour of percolating filters?—Certainly.

21852. (*Chairman.*) Will you kindly give us your figure of the price per cubic yard for washing the material?—I will. I find it is not less than 4s. 6d. per cubic yard for every time the material is washed. To treat 9,000,000 gallons per day I estimate 87,120 cubic yards of beds would be required, and to wash these once every 12 months would cost £19,602, which is approximately £6 per million gallons of sewage treated. Even with the washing of the beds once in every 12 months the original water capacity of the beds cannot be maintained.

21853. (*Colonel Harding.*) Passing on to the question of percolating beds, you agree no doubt that the question of distribution upon percolating beds is a matter of primary importance?—Yes.

21854. And I think in one of your answers—to Question 21682—you refer to some distributor which you yourself have devised, and of which you speak with approval. What are the leading features of it?—The leading feature of that distributor is that it provides for equal distribution of the flow during all conditions of weather.

21855. How does it accomplish it?—Because with other important mechanical advantages in the matter of design it is electrically driven.

21856. You do not depend on the force of the sewage to rotate it, but you have an independent motive power, namely, electricity?—Yes, electricity.

21857. You have no holes through which the sewage passes. Then what is the arrangement of distribution?—Of course, the arms are perforated for the sewage to pass through.

21858. There are holes in the arms?—Certainly.

21859. I thought I gathered that you object to holes as being likely to get stopped up?—Oh, no; my statement in that case only refers to the working parts, not to the arms.

21860. Do you find that they do get stopped up?—No. They get slightly stopped up, but it is not very material.

21861. You have not frequently to clean them?—No.

21862. The special feature of your distributor is that it is driven by an independent motor power?—That is one of its advantages; the others may be better explained by plans and specifications which I shall be glad to submit.

21863. (*Sir William Ramsay.*) In your answer to Question 21684 you say that there should be no small holes. What is the size of the holes in your distributor?—If you take the ordinary distributor there is a number of very small holes, and these get clogged up.

21864. (*Colonel Harding.*) But you say in your answer to Question 21684 that there should be no small holes. You do not object to larger holes?—To larger holes I do not.

21865. (*Sir William Ramsay.*) Might we ask what is the diameter of the holes in your distributor?—They graduate from ¼in. to 1in.

21866. (*Colonel Harding.*) The holes to which you object—in your answer you say there should be no small holes—of what size are they? Are holes 1-16in. to be considered as not small holes?—They are small holes.

21867. Is 1-16in. a small hole?—Yes.

21868. Then you object to that?—Yes.

21869. What size of hole do you find to be practicable?—Between 1in. and ¼in., according to the size and design of the distributor.

21870. But even with ¼-in. holes do you not have some trouble?—No.

21871. I should like again to refer to a point raised by the Chairman on your answer to Question 21687, about the value of open sides to percolating filters. You express a very strong opinion, I think, as to the value of side aeration. I think you said it was based on experiments which you had carried out. Would you mind telling us the nature of the experiment which led you to this conclusion?—The first experiment that I conducted was with a percolating filter enclosed by a brick wall.

21872. What was the size of the filter?—About 40 ft. square.

21873. What depth?—Between 6 ft. and 7 ft.

21874. The walls were quite solid?—Yes.

21875. What was the alternative filter which you compared with it?—Selected clinker.

21876. What was the size of the alternative filter?—40 ft. diameter.

21877. Circular?—Circular.

21878. The other was of the same dimensions all round?—One was a precipitation tank, and the material was put into this; the other was a circular filter with open sides, the filter material formed the sides in larger blocks built up 7 ft. in height.

21879. Was the size of the material in both the same?—Certainly.

21880. Was the liquor put upon both the same?—The same liquor.

21881. You put identical liquor upon practically identical material, the only difference in the construction being that one was circular and the other square, and you found that better results were obtained from the one with open sides than the one with closed sides?—Yes.

21882. To what extent?—It was very slight.

21883. Do you remember sufficiently to be able to say whether it was 10 per cent. better or not?—It was slightly less than that.

21884. Not so much as 10 per cent.?—Oh, no.

21885. We may take it that, though an interesting point, it is not of very great value in your opinion?—I would not say that, but I am bound to say that if I were advising for any scheme I should have open-side filters.

21886. (*Sir William Ramsay.*) What about expense?—Of course, open sides are cheaper, but I am not altogether on the question of cheapness; it is a question of the best results.

21887. (*Colonel Harding.*) I am not in the least questioning the accuracy of the results which you have obtained. What I want to know is upon what your opinion is based—whether the experiments were carried out under identical conditions and whether the distribution in both cases was the same?—You could not get a comparison unless you did that.

21888. They were exactly the same?—Yes.

21889. Was the aeration at the bottom in both cases the same?—Yes, the same.

21890. These were substantially identical parallel filters?—Parallel filters.

21891. Dealing with the same effluent?—The same tank effluent, the same sewage.

21892. And the final result was that you got an improvement which was less than 10 per cent. in the aerated case?—Yes, and as a result I believe that the open side is preferable to the closed.

21893. To that extent?—Yes.

21894. If it was not 10 per cent. do you think it would be 5 per cent.?—You may take it to be from 5 to 10 per cent.

21895. It was more than 5 per cent.—It would average fully 5 per cent.

21896. You are not able to say, therefore, that side aeration, judged from your experiment, was of very great value?—Dealing with experiments is a different question. When you come to a large area—say of putting down a filter an acre in extent—my argument would probably fall through with the larger area, because if you had open sides for an area of an acre the argument in favour of the open sides would disappear; but I am dealing with the smaller area. If you get by the slightest degree a better result from the open sides, on the larger scale.

21897. I shall not be far wrong if I take your answer to mean this—that you think side aeration of some value, though not of great value, and that if filters are carried out on a large scale the value of side aeration becomes less and less as the filters increase in area?—I should still put them in, but the value undoubtedly becomes less. But I should still employ them for the reason that in a question so difficult as that of sewage purification you cannot afford to disregard one single point of apparent advantage.

21898. There is only one other point. You expressed the view that a percolating filter worked equally well in cold weather and in warm, in winter and in summer?—Yes.

21899. Upon what do you base that opinion?—Upon my own results. My percolating filter has been going summer and winter for 3½ years, and the difference in weather is immaterial.

21900. Have you comparative analyses of the percolating filter in times of severe frost and in summer?—Yes, I have them here; I will put them in.

21901. We shall find when we look at those tables that in severe frost you get quite as much purification from a percolating filter as in warm summer weather?—I have continuous records of seven years of the whole, and I have the continuous records of 3½ years of the percolating filter, and the only difference I find that weather conditions make is that which is due to the fact that the sewage is generally weaker in winter than in summer, owing to a large quantity of rain and snow falling during winter.

21902. What is the loss of temperature in passing through your percolating filters?—I cannot give the exact figures offhand.

21903. Would you not be prepared in the abstract to expect that with sewage reduced in temperature to something approaching freezing point there would be less bacteriological action than in sewage with a temperature of 70 degrees?—I would, and I have been surprised to find in my own case that it was not so.

21904. The opinion you have expressed to us is based upon very careful observation and upon analyses which you have placed before us?—Undoubtedly. Other engineers may say that it does make a slight difference. I find, however, that the difference was so immaterial that it could be disregarded altogether. It is no use putting down a scheme if the filters will not work satisfactorily during the year.

21905. (*Mr. Stafford.*) Why do you think that storm overflows ought to be fixed?—They are more reliable. If you have them automatic they get out of adjustment, and will not work.

21906. You prefer them fixed?—Yes.

21907. In answer to Question 21607 you say that you prefer to use settlement tanks in parallel rather than in series. Why is that?—Tanks in parallel provide for a more equal distribution of the sludge than those in series.

21908. In reply to Question 21639 you say it is not advisable to pass the storm water through the septic tanks. Why do you consider it not advisable?—Because storm water invariably comes down with too great a rush into the septic tank, thereby interfering for a time with septic action, and therefore I think the best results are obtained by putting the storm water after a certain flow comes down on the special filters provided for the purpose.

21909. In answer to Question 21663 you say that the first flush of storm sewage, which is very polluting, should not be allowed on to the beds, but afterwards, as the sewage becomes more dilute, five or six fillings a day may be given with fairly good results. Could you use your beds for any length of time with five or six fillings a day?—Yes, for the length of any storm at least.

21910. Contact beds?—These storm beds are coarse filters?—They are.

21911. (*Major-General Carey.*) With reference to Question 21667, how is the average working capacity to be maintained if the material cannot be washed?—I could not say, the hydraulic value must in that event necessarily decrease.

21912. (*Sir William Ramsay.*) What is the acid that is present as mentioned in your answer to Question 21593—is it sulphuric acid?—Yes, chiefly, and some others from the dye-works.

21913. Is it sulphuric acid employed in making plates?—Yes. Wire drawing or galvanising.

21914. I understand that your sewage is rather fatty, is it not?—There is a good deal of fat.

21915. Is that what makes it combustible, so that you can dry it and burn it?—I do not think so. You can burn it; it is only a question of getting a little extra fuel. The fat helps to burn undoubtedly, but if the fat was less I think I should be able to burn the sludge after being pressed all the same.

21916. Will the sludge burn of itself, or do you require to mix fuel with it?—I mix with it a very small quantity of coke breeze, or in the absence of coke breeze I use house refuse—the cinders that are collected by the scavengers' carts from the houses. It will not burn of itself; it wants a little assistance.

21917. Have you ever estimated what it is worth as fuel?—I suppose you could put a price on it as fuel; very little, if any.

21918. Would it not be worth while to ascertain whether you lose very heavily on pressing and drying the sludge, as against the cost of burning it? You are saving fuel by burning the sludge, though probably your gain is much less than your loss by drying and pressing the sludge?—The process of drying, pressing, and burning is a heavy item inclusive.

21919. Not the process of burning; you gain by that; you save fuel. The process of drying and pressing is expensive?—It is expensive even then.

21920. (*Colonel Harding.*) Can you give us any figures as to the cost of pressing and burning?—Yes; it runs to about 5s. per ton of cake produced. That is a fact that I know, because I have tested it times without number over extended periods, and cannot get the cost less. I have erected specially two of the best furnaces in the country for the burning of sludge, and cannot make any reduction in the cost of burning.

21921. That is clearly not prohibitive, because you are proposing to do it?—It is not prohibitive, although the cost is somewhat heavy.

21922. (*Sir William Ramsay.*) The cost of pressing and drying is 5s. per ton. What is the cost of burning—you naturally get something out of that?—The cost of pressing and drying is at the rate of 2s. 6d. per ton, and the cost of burning another 2s. 6d., making a total of 5s. per ton exclusive of the value of steam produced,

Mr. K. F. Campbell, M.Inst.C.E.

10 May 1905.

which may be disregarded altogether in such cases; it is quite a nominal figure.

21923. Granted; but what do you make? How much do you save in coal by burning sludge? Is it worth 2s. as coal?—Much less.

21924. What then?—Nothing, for that matter.

21925. (*Colonel Harding.*) Would it not contain 50 per cent. of moisture?—Yes, it would.

21926. (*Sir William Ramsay.*) You said it would not work for distillation. If it had much fat in it would it not pay for distilling?—Some people believe that there is something in that—extracting the fat and oil. That is a question I am going into, because it is worth trying, and experiments are now in progress.

21927. (*Colonel Harding.*) There is, of course, a very large quantity of residual ash?—Yes.

21928. What becomes of it?—It is very useful to me at present, so far as the clinker is concerned, because I have to prepare a large area of percolating beds for which the clinker is specially adapted.

21929. So that you are really producing material for your beds, and that must be taken into consideration?—Certainly.

21930. It may be put to the credit side, and so reduce the cost which you told us?—Yes.

21931. To what extent?—The estimates which I have got in for my larger scheme are at about 5s. per cubic yard for the filter material which I require.

21932. And this forms filter material?—A certain proportion of it—not more than one-third of it. A good deal of it is ash; a good deal of it disintegrates, and you can only select the best clinker, which is honeycombed and substantially hard and durable.

21933. That is a very valuable point. Are you able to tell us about what proportion of useful material you can obtain from a ton of cake?—About one-third of the quantity.

21934. One-third of the ton?—You mean the proportion of it?

21935. Suppose you had a ton of cake, how much material do you think you could obtain?—About one-third of a ton residue; of that quantity nine-tenths is rather fine material unsuitable for beds, and one-tenth adapted for such purposes.

21936. It is a very important point. If the farmers will not take your cake, and you have to dispose of it, and can do so by burning it, and if by so doing you produce what is useful to you—if that is practicable from a financial point of view—it is an important result?—The clinker has another value; there is nothing better for ground mortar, making street foundations, and so forth. Therefore it has other advantages. I am not going to say that clinker is all waste—far from it.

21937. (*Sir William Ramsay.*) In your answer to Question 21653 you say that one acre is the most convenient size for a contact bed. What is the most convenient size for a percolating filter?—One acre.

21938. Would you have the same size?—Yes, for the reason that the sewage can with certainty be economically and properly applied to each filter.

21939. Do you not find great difficulty in distributing over an area of an acre?—No. With a properly constructed distributor such as I have designed for Huddersfield it can be done perfectly satisfactorily. The Local Government Board have had it under supervision, and have approved of it. I should be glad to send it down to the Commission for them to see it.

21940. In answer to Question 21702 you say that beyond some little time for cleaning and repairing the sprinkler no attention is needed. Is it a fair question to ask how often the sprinkler does require to be cleaned and repaired—is it a frequent process?—It is not a frequent process. The sprinkler should operate successfully for several months. In cases where there is a large installation with irregular flow there must of a necessity be more sprinklers employed upon the work than the ordinary flow requires. In such cases the little attention required in cleaning the arms of the sprinkler can if necessity requires be done by the ordinary staff when the sprinkler is at rest.

21941. So that there is no special stoppage?—No.

21942. In using these percolating beds do you find that they require washing through every now and then?—I have never washed mine for 3½ years.

21943. Not by an extra large supply of water?—No, I never pour water through them.

21944. Do you settle the effluent from these percolating beds, or is it merely a proposal that it might be done?—A proposal to be followed in practice.

21945. You do not do it at present?—No, but I think it should be done; in fact, we are making provision for it now in our new scheme for giving the effluent two hours' settlement before discharging into the river.

HUDDERSFIELD.

Appendix to Evidence of Mr. K. F. Campbell.

Tables showing average analyses of sewage, tank liquors, and filter effluent at Huddersfield.

PROCESSES OF TREATMENT:

(*a*) Chemical Precipitation and Double Contact Beds.

(*b*) Septic Tanks and Double Contact Beds.
(January, 1903, to June 17th, 1903)
(and January 14th, 1904, to December, 1904.)

(*c*) Sedimentation Tanks and Double Contact Beds.
(June 18th, 1903, to January 13th, 1904.)

(*d*) Continuous Filtration after Septic Tanks.
(January, 1903, to June 17th, 1903)
(and January 14th, 1904, to December, 1904.)

(*e*) Continuous Filtration after Sedimentation.
(June 18th, 1903, to January 13th, 1904.)

HUDDERSFIELD.

Average Analysis of Sewage.

———	Best (Sunday.)	Worst.	Average for Weekdays.
Ammoniacal nitrogen as NH_3	·20	1·60	1·10
Albuminoid nitrogen as NH_3	·111	·990	·60
Nitric nitrogen	—	—	—
Chlorine	2·9	15·1	11·9
Oxygen absorbed from $KMnO_4$ in 4 hours	2·26	14·2	10·7
Dissolved oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 20.

TANKS—

Precipitation Tanks—

Average flow through tanks per 24 hours (5½ hours) - 5,343,000 gallons.
Amount of sewage precipitated during the month - 149,610,000 gallons.
Amount of chemicals used during the month { Lime - 20 tons 10 cwts. / Copperas - 12 tons 19 cwts.
Amount of sludge dealt with during the month - 123,840 cubic feet = 3,591 tons.

Average Analysis of Precipitation Liquor.

———	Best.	Worst.	Average.
Ammoniacal nitrogen as NH_3	·30	1·51	1·07
Albuminoid nitrogen as NH	·064	·354	·249
Nitric nitrogen	—	—	—
Chlorine	—	—	—
Oxygen absorbed from $KMnO_4$ in four hours	1·89	6·86	5·49
Dissolved oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 20.

Septic Tanks—

Average flow through the tanks per 24 hours (24 hours) - 55,000 gallons.
Amount of sewage treated in tanks during month - 1,540,000 gallons.
Amount of sludge dealt with from this process during month - none.

Average Analysis of Septic Liquor.

———	Best.	Worst.	Average.
Ammoniacal nitrogen as NH_3	—	1·69	1·60
Albuminoid nitrogen as NH_3	—	·45	·359
Nitric nitrogen	—	—	—
Chlorine	4·1	16·6	12·1
Oxygen absorbed from $KMnO_4$ in 4 hours	3·0	8·11	6·53
Dissolved oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 20.

FILTERS—

Contact Beds after Chemical Treatment—

Number of times primary beds were filled during month - - - - 68
Number of times secondary beds were filled during month - - - - 68
Estimate of amount of tank liquor treated per cube yard per 24 hours - - 84 gallons, 6 days per week.

Average Analysis of Filter Effluent.

——	Best.	Worst.	Average.
Ammoniacal nitrogen as NH_3	·14	·16	·16
Albuminoid nitrogen as NH_3	·024	·090	·059
Nitric nitrogen	—	—	—
Chlorine	6·9	16·6	13·0
Oxygen absorbed from $KMnO_4$ in 4 hours	·41	1·44	1·06
Dissolved oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 20.

Contact Beds after Septic Treatment—

Number of times primary beds were filled during month - - - - 69
Number of times secondary beds were filled during month - - - 69
Estimate of amount of tank liquor treated per cube yard per 24 hours - - 73 gallons, 6 days per week.

Average Analysis of Filter Effluent.

——	Best.	Worst.	Average.
Ammoniacal nitrogen as NH_3	.20	·26	·21
Albuminoid nitrogen as NH_3	·036	·131	·081
Nitric nitrogen	—	—	—
Chlorine	8·4	16·6	12·9
Oxygen absorbed from $KMnO_4$ in 4 hours	·63	1·67	1·24
Dissolved oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 20.

Continuous Filter—

Number of hours filter worked during the month - - - - - - 384
Amount of tank liquor treated per cube yard per 24 hours - - - - 132 gallons, 6 days per week.

Average Analysis of Effluent.

——	Best.	Worst.	Average.
Ammoniacal nitrogen as NH_3	·46	·71	·51
Albuminoid nitrogen as NH_3	·069	·149	·093
Nitric nitrogen	—	—	—
Chlorine	7·1	16·5	12·7
Oxygen absorbed from $KMnO_4$ in 4 hours	·7	1·97	1·4
Dissolved oxygen taken up in 24 hours	—	—	—
Suspended solids	—	—	—

Number of samples analysed for the average = 20.

SEVENTY-FOURTH DAY.

Thursday, 11th May, 1905.

PRESENT.

The Right Honourable the Earl of Iddesleigh (*Chairman*) presiding.
Major-General Constantine Phipps Carey, C.B., R.E.
Colonel T. W. Harding, J.P.
Sir William Ramsay, K.C.B., F.R.S.
Mr. W. H. Power, C.B., F.R.S.
Mr. T. J. Stafford, F.R.C.S.I.

Mr. F. J. Willis (*Secretary*).

ALSO PRESENT.

Dr. A. C. Houston.
Dr. George McGowan.
Mr. G. B. Kershaw.
Mr. C. C. Frye.

Mr. W. H. Harrison, M.Sc., called in ; and Examined.

Mr. W. H. Harrison, M.Sc.

11 May 1905.

21946. (*Chairman.*) You are Mr. W. H. Harrison, Chemist to the Leeds Corporation Sewage Works ?—Yes.

21947. And you have come before us to-day to give evidence with regard to your experience of the treatment of sewage, with special reference to the Leeds Sewage Works ?—Yes.

21948. What is the general system of sewage treatment at Leeds ?—The bulk of the sewage is treated by precipitation in continuous settlement tanks, and a small proportion is treated in septic tanks, and by means of various comparatively small bacteriological filters.

21949. What is the population draining to the Leeds Works ?—The population of Leeds at the last census (1901) was 428,968, and the estimated population in June, 1904, was 450,142. The Sewage from the whole drains to Knostrop Sewage Works, with the exception of a small portion which drains to the Rodley Works.

21950. What is the system of drainage ? That is to say, is the storm water either wholly or partially drained into a separate system, and if only partially, to what extent ?—Storm water and the ordinary sewage both enter the same system of sewers.

21951. Is there any infiltration of subsoil water into the sewers ?—There is some infiltration of subsoil water, but its presence is only felt after long periods of wet weather. At ordinary times the amount entering the sewers is very small.

21952. What is the water supply per head, and from what source does it come ?—The present water supply is 36 gallons per head of population per day, being practically 16,000,000 gallons per day, *i.e.*, almost equal to the dry weather flow of sewage. The collecting ground for the Leeds water supply is the area draining into the river Washburn, a tributary of the Wharfe.

21953. Is it hard or soft water—The water is soft. The total hardness is equal to 5·0 parts of $CaCO_3$ per 100,000.

21954. What is the drainage area of the part of the town which is sewered ?—The City of Leeds has an area of 21,572 acres and most of this is drained. Part of the area, comprising 1,500 acres, is tributary to Rodley.

21955. What proportion of the population use pail closets or middens and what proportion use water-closets ? —About three-fourths of the population use water closets or trough (water) closets, and the rest privies. The latter are being replaced by water closets which are now compulsory in new buildings.

21956. Has the flow of sewage to your works been gauged ? If so, what is the average number of gallons delivered at the works per day of 24 hours in dry weather, in winter, and in summer ?—The average of gaugings taken 3 years ago in dry weather showed the sewage flow to be between 15-16 million gallons per 24 hours. There is no great difference between the dry weather flow in summer and in winter.

21957. What is the maximum dry weather rate of flow and at what hour does this occur ?—The maximum dry weather rate of flow is about 26,000,000 gallons per 24 hours, and occurs usually about 10 a.m.

21958. What is the minimum dry weather rate of flow, and at what hour does it occur ?—The minimum flow occurs about 4 a.m. and is at the rate of 10,500,000 gallons per 24 hours. The hourly variation in the rate of flow during the 24 hours is as follows :—

Time	Rate of Flow in Galls. per 24 hours.
7 a.m.	11,300,000
8 a.m.	12,000,000
9 a.m.	12,000,000
10 a.m.	26,200,000
11 a.m.	22,500,000
12 (noon)	22,500,000
1 p.m.	22,500,000
2 p.m.	19,900,000
3 p.m.	19,100,000
4 p.m.	19,100,000
5 p.m.	19,900,000
6 p.m.	23,400,000
7 p.m.	20,800,000
8 p.m.	20,800,000
9 p.m.	19,900,000
10 p.m.	19,000,000
11 p.m.	19,000,000
12 (midnight)	19,000,000
1 a.m.	11,300,000
2 a.m.	11,300,000
3 a.m.	11,300,000
4 a.m.	10,600,000
5 a.m.	12,000,000
6 a.m.	12,000,000
Average	17,300,000

21959. What is the maximum wet weather rate of flow which you have observed coming to the works, and during how many hours has this continued ?—The main outfall sewer has a maximum capacity of 60 million gallons per 24 hours and a very slight rainfall (about $\frac{1}{20}$ in. per hour fills it to its full capacity. Thus the maximum wet weather flow is often reached during the course of a year, the duration of any such flow being coincident with the continuance of the rainfall.

21960. Does the infiltration of subsoil water into the sewers occur regularly, or does it vary with the seasons or with the state of the weather; and can you give an approximate idea of the extra amount of liquid at one and another time entering the sewers from this source ?—The infiltration of subsoil water into the sewers varies with the state of the weather, *i.e.*, in dry weather practically no subsoil water is present, but after a heavy rainfall it is present for some time. During these latter periods the maximum amount entering the sewers will be about three million gallons per day.

Mr. W. H. Harrison, M.Sc.

11 May 1905.

21961. How many gallons of trade effluents enter the sewers daily, and what is the nature of these effluents? If you have analytical figures, please give them?—One third of the water supply is used for trade purposes and practically the whole of this enters the sewers. In addition some few works possessing their own wells have access to the sewers. The total amount received will be about 6 million gallons per day. In the City of Leeds will be found representatives of most trades and manufacturing processes, so that together they produce a very complex mixture of trade refuse. The chief effluents however are those from Tanneries, Dye-Works, Copper and Galvanizing Works, Vitriol Works, Ammonia Works, etc., and some Wool-scouring Works.

One trade effluent from an Ammonia Works gave the following analysis:—

	Per cent.
Loss on ignition	42
CaO (free in solution)	5
CaO (in combination)	30
Cl as chloride	17

These figures are calculated on the dry solids. This liquid exerted a strong precipitating action on sewage and contained solids in solution to the extent of 2,220 parts per 100,000. Another effluent from a Vitriol Works contained 14,500 parts of $FeSO_4$ per 100,000 as well as very large quantities of Na_2SO_4 and NaCl. Another liquid which has come under examination contained 12 per cent. of free sulphuric acid and As_2S_3 in suspension to the extent of 1,530 parts per 100,000.

21962. Have the Corporation framed any rules for the reception of trade effluents into the sewers?—The admission of trade refuse to the sewers is conditional upon (*a*). The adoption of efficient means for removing the solids from the refuse; (*b*.) The discharge to be so regulated as as to be spread equally over the 24 hours; (*c*.) The provision of an inspection manhole.

*21962. Do you find that the trade effluents interfere with the process of purification by reason of their quality, variations in composition, fluctuations of volume, or otherwise?—The experience at Leeds is that if the trade effluents are free from suspended solids, are admitted at a uniform rate over the 24 hours, and are not great in volume compared to the domestic sewage, no difficulty is experienced in treating the mixed sewage. Strong dye-liquors if treated on filters without the previous use of a septic tank, discolour the filtrate, and cause inefficient oxidation and æration. This is not apparent when they are diluted by being discharged evenly over the 24 hours, especially when septic tanks are used. The iron liquors received into the Leeds sewers are chiefly in the ferrous state, and when discharged in bulk into the sewers at irregular intervals, a large proportion of the iron reaches the works in the reduced condition. In this state, having a great affinity for oxygen, the filtrate is usually deteriorated in quality and the nitrification values are low. The filtrates from contact beds are strongly yellow and often separate out flocculent basic iron-compounds producing a very unsightly condition. A large part of the iron is separated out of solution in the filters and cements the bed material into large impervious masses. With trickling filters there is practically no iron present in solution in the filtrates, the iron coming away from the filter with the suspended matter, and the latter in consequence being granular, easily settled, and less liable to putrefaction. The septic tank and precipitation processes are useful in these cases due to the removal of a large proportion of the iron from solution before filtration.

21963. In dry weather what is the average amount of suspended matter in your sewage, and what are the highest and lowest figures, in parts per 100,000?—The average amount of suspended matter in our sewage for the years 1903–1904 is 60·1 parts per 100,000; the highest value obtained being 104 parts in September, 1903, and the lowest 33·5 parts per 100,000 in August, 1904.

21964. What is the physical character of these solids?—The suspended solids are more or less dark brown in colour and the bulk of them easily coalesce into flocculent masses and therefore are fairly easy to settle out. The remainder is very finely divided and only separates out very slowly.

21965. Can you give us average analyses of the sewage for the years 1903 and 1904 in summer and in winter?—Yes, the average analysis for the years 1903 and 1904 was:

	Parts per 100,000.
Ammoniacal Nitrogen	1·84
Albuminoid Nitrogen	·602
Oxygen absorbed in four hours at 80° F.	10·8
Suspended Solids	60·1
Soluble Solids	102·2

I hand in a table showing the averages in winter and summer for 1903 and 1904.

	1903.		1904.	
	Winter—Jan., Feb., Nov., Dec.	Summer—June, July, Aug., Sept.	Winter—Jan., Feb., Nov., Dec.	Summer—June, July, Aug., Sept.
Ammoniacal nitrogen	1·91	1·99	1·78	1·87
Albuminoid nitrogen	·601	·584	·633	·619
Oxygen absorbed at 80 °F. in 4 hours	9 44	13·0	8·35	11·0
Suspended solids	55·3	77·5	63·9	49·8
Soluble solids	106·8	106·8	97·7	102·2

21966. Is it a "strong sewage," and, if so, what characterises its strength?—The sewage of Leeds is not strong with regard to organic impurity, but its treatment is complicated by the presence of one-third its volume of trade refuse.

21967. Does its strength vary very much from hour to hour or on different days of the week, and, if so, do these variations affect the quality of your final effluent to a marked degree?—The strength of the sewage varies, but not to the same extent as when the bulk of the Trade refuse entered in flushes. Then, as I have before stated, the filtrates were affected by the varying amounts of the refuse in the sewage. That this refuse does affect the purification is shown in the treatment of Sunday and holiday sewages, which give much better results than normal. It is impossible at Leeds to compare different sewage strengths without referring to the amount of refuse present.

21968. Are there any chemical poisons in the sewage? If so, what are they, and to what extent do they occur?—Poisons do not occur to any great extent in the Leeds sewage. The chief being Arsenic Sulphide and a comparatively small amount of Thiocyanates.

21969. Is the sewage always alkaline?—Normally the sewage is neutral to litmus. The presence of an unusual proportion of trade refuse may make it slightly

acid or alkaline as the case may be, but not to a very appreciable extent.

21970. Do you find that the amounts of suspended solids are increased or diminished in times of storm; and can you give the Commission the figures at the end of each hour during a storm of some hours duration?—The following analytical data on the composition of storm water sewage was collected some time ago. (*a*) Average analysis of storm water sewage made during four periods of storm, each storm being over twenty hours duration. The average duration was twenty-eight and a half hours:—

Ammoniacal Nitrogen	·856
Albuminoid Nitrogen	·259
Oxygen absorbed in four hours at 80° F.	6·37
Suspended Solids	56·8
Soluble Solids	60·4

(*b*). Average of five storm water sewages, the average duration of each storm being thirteen and a quarter hours.

Ammoniacal Nitrogen	1·04
Albuminoid Nitrogen	·318
Oxygen absorbed in four hours at 80° F.	6·85
Suspended Solids	58·4
Soluble Solids	66·0

(*c*). Average of eight storm water sewages having an average duration for each storm of seven and a half hours.

Ammoniacal Nitrogen	1·26
Albuminoid Nitrogen	·435
Oxygen absorbed in four hours at 80° F.	9·87
Suspended Solids	67·2
Soluble Solids	73·4

Generally speaking the amount of suspended matter in storm sewages varies directly with the hourly rate of rainfall. A comparison of the above averages with those of the sewage shows that on the average storm waters contain practically the same amount of suspended matter as ordinary sewage. The amount of organic impurity present is however much smaller. The suspended solids in storm-waters caused by short heavy rain-storms are usually very high.

21971. What is the character of the liquid part of the sewage in storm times? Perhaps you could illustrate this answer by analyses of the liquid portion of the sewage in dry weather and in storm times?—I am not able to give analytical data of the liquid part of storm-waters produced either by settlement or filtration, but I can give an average analysis of a liquid produced by the precipitation of storm waters with one grain of sulphate of alumina and three grains of lime per gallon which may be of interest. The sewage remained in the tank for a period of four hours:—The analysis was:

Ammoniacal Nitrogen	1·14
Albuminoid Nitrogen	·160
Oxygen absorbed in four hours at 80° F.	2·18
Suspended Solids	9·0
Soluble Solids	59·4

Precipitated sewage, during the same months, precipitated with two grains sulphate of alumina and 6 grains of lime per gallon, and with an eight hours stay in the tank, gave an average result of:—

Ammoniacal Nitrogen	1·87
Albuminoid Nitrogen	·345
Oxgyen absorbed in four hours at 80° F.	4·38
Suspended Solids	9·7
Soluble Solids	101·0

21972. In what way or ways do you think the sewage which comes to the works should be dealt with in storm times? Perhaps I should amplify this question a little. The usual requirements of the Local Government Board are, I understand, that any increase in flow up to three times the normal dry weather rate should be fully dealt with by the ordinary complete plant, and that a certain number of additional dilutions—up to a total of six—should be treated on special storm filters. Do you think these are proper requirements, or do you think they should be modified in any way? It is, I believe, often found that the storm sewage which first comes down to the works contains a largely-increased amount of suspended solids, and I should like to know whether you consider that your ordinary (dry weather) plant is exposed to damage in any way—as, *e.g.*, rapid choking, by having to deal with this amount of storm sewage, and whether you think it would be better to adopt some other treatment. Although the storm sewage, including the suspended solids, is a very polluting liquid, possibly the liquid portion alone is not very polluting, and this suggests that settlement of all the sewage arriving at the works in time of storms in tanks for a few hours after, possibly, the addition of chemicals, might perhaps be a better plan of treatment than passing a portion of it through the ordinary plant, and the balance through storm filters. Would such settlement alone be sufficient for the whole of the sewage arriving at the works in times of storm?—I am in general agreement with the provisions laid down by the Local Government Board for the treatment of storm waters especially that the storm water should undergo some method of treatment previous to entering a water course. As I have already shown storm waters, when deprived of most of their suspended matters, are not excessively polluted, consequently in the case of entry into non-drinking streams having a large volume in proportion to the sewage flow I think the case would be fully met by treating three volumes as in the ordinary way, the remaining three volumes being well settled or precipitated. At Leeds it has been found possible to treat the whole six volumes of storm water when well precipitated, upon a continuous filter having a depth of six feet and at ordinary times treating precipitated sewage at the rate of 100 gallons per square yard per twenty-four hours; the filtrate at such times being excellent in character, and being fairly free from suspended matter can be sent direct into a stream. The average analysis of this storm filtrate from July to December, 1904, was:—

Ammoniacal nitrogen	·357
Albuminoid nitrogen	·103
Oxygen absorbed in 4 hours at 80° F.	1·05
Suspended solids	7·1
Incubator test	before ·310 after ·320
Nitrogen as nitrate	1·39

Normal rate = 100 gallons per square yard. Storm water rate = 600 gallons per square yard.

Depth of filter 6 ft.

The occasional treatment of this large volume of liquid does not seem to affect the subsequent normal filtrates. Recent experiments point to the possibility of successfully treating all the six dilutions of storm waters after precipitation upon a 6 ft. continuous filter at the rate of 1,200 gallons per square yard. The average of the March, 1905, analysis is:—

Ammoniacal nitrogen	·514
Albuminoid nitrogen	·108
Oxygen absorbed in 4 hours at 80° F.	·860
Percentage of dissolved oxygen absorbed in 24 hours	27%
Nitric nitrogen	1·13
Suspended solids	8·1

Normal rate of filter 200 gallons per square yard. Storm water rate = 1,200 gallons.

Depth of filter = 6 ft.

This filtrate compares very favourably with the filtrate produced from a specially constructed storm-water filter filtering screened storm water at the rate of 500 gallons per square yard per 24 hours:—

Ammoniacal nitrogen	·460
Albuminoid nitrogen	·161
Oxygen absorbed in 4 hours at 80° F.	2·43
Suspended solids	14·4
Incubator test	before ·495 after ·581
Nitric nitrogen	·824

In the case of another filter 12 ft. deep and normally treating screened sewage at the rate of 200 gallons per square yard per day a similar series of experiments were instituted, the storm water being merely screened before being sent on to the filter. The rates of filtration varied from 600 to 1,200 gallons per square yard per 24 hours. The results are as follows: (*a*) The filtrate during storm

Mr. W. H. Harrison, M.Sc.

11 May 1905.

times contained large quantities of suspended matter and was invariably putrescent, but after removing these suspended matters by straining through ashes a non-putrescent result was obtained. Naturally the higher rate of flow gave the worst results. The averages for 24 of these experiments were :—

	Unfiltered filtrate.	Filtered filtrate.
Ammoniacal Nitrogen - -	·558	·451
Albuminoid Nitrogen - -	·415	·089
Oxygen absorbed 4 hours at 80° F.	7·08	·921
Suspended solids - - -	59·2	—
Nitric nitrogen - - -	·027	·042
Absorption of dissolved oxygen in 24 hours - - -	100%	45%

(*b*) It was evident that these heavy doses of storm water have a deleterious effect upon the normal working of the filter, especially with the higher rate of flow. The filter, however, soon recovers itself, and with the lower rate of flow no difficulty should be experienced.

I have no experience in the treatment of storm water on contact beds with the exception of the special storm filters referred to. Briefly stated, my views are that storm waters up to three dilutions should undergo some efficient process before admission to a stream. That if nearly all solids are removed, then the six volumes of storm water may be treated on the ordinary plant, and if some solids are allowed to remain in the storm water, three volumes can be treated on the ordinary plant and the remainder by special storm filters, settlement, or precipitation. These remarks I intend to apply only to continuous filters and to comparatively weak sewages.

21973. Is your sewage settled, and, if so, how; *i.e.*, by quiescent settlement or continuous settlement; and what length of time does it stay in the tanks or take to pass through, as the case may be ? Would you kindly give an average analysis of the tank liquor, including the figures for suspended solids ?—The bulk of the sewage at Leeds is precipitated and settled continuously. Experimentally a small amount of sewage (about 45,000 gallons per day) is treated by continuous settlement without the addition of chemicals. The rate of flow through the tank was 4 hours from February to May and from August to September, 1904. The average analysis for these periods was :—

Ammoniacal nitrogen	1·60	parts per 100,000
Albuminoid nitrogen	·372	„ „ „
Oxygen absorbed in 4 hours at 80° F.	5·24	„ „ „
Soluble solids	91·7	„ „ „
Suspended solids	12·8	„ „ „

From June to July, 1904, and from October, 1904 to February, 1905, the rate of flow was 8 hours. The average of all analyses for this period was :—

Ammoniacal nitrogen	1·90	parts per 100,000
Albuminoid nitrogen	·413	„ „ „
Oxygen absorbed in 4 hours at 80° F.	5·84	„ „ „
Soluble solids	105·4	„ „ „
Suspended solids	11·7	„ „ „

21974. Have you data to show what proportion of the suspended matter in the Leeds sewage is settled in ½ hour, 1, 2, 3, 4, 5, 6, 12, and 24 hours, if the sewage is given quiescent settlement ?—Several experiments upon the quiescent settlement of sewage have been performed at Leeds in a tank having a capacity of 250,000 gallons. The following is a summary of the results obtained.

Date.	No. of Experiments.	Average amount of Suspended Solids (parts per 100,000).						
		in Sewage	¼ hr.	½ hr.	¾ hr.	1 hr.	1½ hrs.	2 hrs.
Mar. 10th & 11th, 1903 -	4	70·0	—	13·4	—	12·7	9·1	10·7
Mar. 16th & 17th, 1903 -	4	46·4	14·4	11·2	7·2	6·7	6·5	—

Experiments upon the quiescent settlement of limed sewage (3 grains per gallon) gave practically the same results.

21975. What time would be necessary for you to gain a good tank liquor containing, say, no more than six or eight parts of suspended solids per 100,000 from your sewage (without the addition of chemicals), by quiescent settlement, and by continuous flow settlement ?—Generally speaking two hours quiescent settlement will reduce the suspended solids to 8—10 parts per 100,000, and with continuous settlement about a twelve hours rate of flow would be advisable.

21975A. Do you prefer to use settlement tanks in series or in parallel ?—When a large volume of sewage is treated daily by continuous flow I prefer to use the tanks in parallel series of three to four. If all the tanks are in one series there is danger of the rate of flow becoming excessive and preventing the finer particles from settling out. In the case of quiescent settlement, I prefer the tanks in parallel.

21975B. In the case of continuous flow tanks, do you think there is any advantage in the employment of baffling boards or walls ?—Baffling boards or walls should be installed in several of the tanks to prevent a surface flow taking place.

21975C. How is the sludging done at your works and what is the character of the sludge ? Does any nuisance attend the operation ? Have you means of storing sludge, or do you have to get rid of it as soon as it is removed from your tanks ?—The tank to be cleaned out is isolated from the series by means of dam-boards and the liquid contents are run off by a special valve back to the pump-well. The sludge is then allowed to flow into a culvert—manual labour being required to push the sludge towards the valve—which gravitates to a sump. The sludge is pumped out of the latter into a small lagoon and allowed to stand at rest for twenty-four hours, during which period as much water is drained off as possible. From this lagoon the sludge gravitates into another lagoon of larger dimensions where a period of rest of two to three days is allowed and all water possible removed. The sludge which now contains from 80 to 85 per cent. water is run into the large lagoons, which when full are allowed to drain until the contents are spadeable, when they are removed and stored in heaps for the farmers to take. The sludge when freshly drawn from the tanks contains 90 to 92 per cent. water and runs in channels freely. Apart from the culvert no nuisance arises during these cleansing operations and certainly no smell from the culverts is appreciable in the open air. The sludge drying in the lagoons does give rise to smells, which however are not noticeable at a short distance from the lagoons. No serious complaints have been made.

21976. Should the heavy (road detritus, etc.) portion of the suspended matter in sewage be removed as a first operation, or do you think it better and more economical to let everything settle in the tanks, and subsequently to screen the sludge ?—With the foregoing method of dealing with sludge, I find it quite practicable to allow the road detritus to settle out in the tanks. All the heavy matter settles out around the inlet into the first tank, taking the form of a cone and thus allowing the ordinary sludging operations to be performed. This detritus is wheeled out of the tank after the ordinary sludge has been removed.

21977. You have had experience of the chemical precipitation of sewage ?—The method of treating the

bulk of the Leeds sewage is by precipitation with lime and this process has been in operation for many years. Experimentally other precipitants, either alone or in mixture have been used.

21978. Have you any reason to think that sewage from which the solids have been removed by the aid of chemicals is less easily purified by subsequent filtration than sewage from which the solids have been removed by settlement or by passage through septic tanks? — Recent experiments at Leeds have shown that an effluent, produced by using eight grains of lime per gallon and two grains of sulphate of alumina and practically free from suspended matter, can be treated more easily than septic tank effluent or settled sewage upon trickling filters. This is due to the much smaller amount of suspended matter sent on to the filter. Thus in March, 1905, the results were:— *Mr. W. H. Harrison, M.Sc.* 11 May 1905

	Filtrate from filters. Treating settled sewage.		Filtrate from filter. Treating precipitated sewage.
	Unsettled.	Filtered.	
Ammoniacal N.	·420	·336	·500
Albuminoid N.	1·26	·041	·070
Nitric N.	1·60	2·15	1·52
Oxygen absorbed in four hours at 80° F.	1·39	·471	·581
Percentage of dissolved oxygen absorbed in twenty-four hours	·18	·5	·13
Suspended Solids	10·5	1·7	·8
Amount treated per cubic yard per twenty-four hours	61 galls.		100
Depth of filter	9ft. 6ins.		6ft.

The same filters treating the same liquids, but with the 6ft. bed, treating precipitated sewage at the rate of 49 gallons per cubic yard per day gave average results for 1904 of:—

	Filtrate from filter. Treating settled sewage.		Filtrate from filter. Treating precipitated sewage.
	Unsettled.	Filtered.	
Ammoniacal N.	·295	·253	·310
Albuminoid N.	·137	·070	·069
Nitric N.	1·27	1·42	1·81
Oxygen absorbed in four hours at 80° F.	1·64	·945	·69
Percentage of dissolved oxygen absorbed in twenty-four hours	32·8	15·7	10·3
Suspended Solids	12·9	6·4	2·1
Amount treated per cubic yard per day	61galls.		49
Depth of filter	9ft., 6ins.		6ft.

21979. Have you tried various chemicals. Can you give any comparative data on the practical value and cost of different precipitants for the preliminary treatment of sewage?—Several precipitants have been tried upon Leeds sewage in order to obtain their relative values, but the question of cost has not been considered. The most effective precipitant was a mixture of ferric salts and lime closely followed in merit by aluminium sulphate and lime. These two precipitants were almost equally effective and were followed in order of merit by alum and lime, ferrous sulphate and lime, ferric salts, alum and ferrous sulphate. The last was practically valueless.

21980. What is the most effective way of adding chemicals?—Lime is best added in the form of lime water, but, as owing to the large volume of water required this is impracticable, recourse should be had to a weak milk of lime. The other chemicals where possible should be used in solution. To obtain the best results the amount of precipitant added should vary with the strength and volume of the sewage.

21981. What is the average analysis of the liquor from your precipitation tanks? What length of time does the sewage remain in the tanks?—The average for the years 1903 and 1904 is:—

Ammoniacal Nitrogen	1·68
Albuminoid Nitrogen	·306
Oxygen absorbed, 4 hours at 80° F.	4·61
Suspended Solids	11.1
Soluble Solids	98·9

The time the sewage remains in the tanks varies from about 3 hours to 6½ hours according to the rates at which the sewage is flowing through them, the average time being rather over four hours, only 3 grains of lime per gallon being used.

21982. Do you find it necessary to add further chemicals to the sludge before it can be dealt with?—No addition of chemicals to the sludge is necessary when it is dried in lagoons.

21983. What is the character of the suspended matter in the precipitation tank liquor?—The suspended matter in the effluent is very finely divided and settles out only very slowly. It is putrescent.

21984. What is the manurial value of the sludge obtained by the chemical precipitation of sewage at your works, and will farmers take it?—The manurial value of the sludge produced at these works is low as shown in the following analysis of the dried substance:—

	Per cent.
Loss on ignition	51·90
Sand and insoluble matter	16·97
Fe_2O_3 and Al_2O_3	14·12
CaO	12·11
S. as sulphate	·36
S present otherwise than sulphate	2·75
P_2O_5	1·16
The total nitrogen was	2·64

A certain proportion, about $\frac{1}{5}$ of the total production, is removed by the neighbouring farmers and rhubarb growers, who use it more as a rich earth than as a manure. There is no difficulty with the disposal of screenings, etc., as this is a good material for hot-beds. No doubt if greater facilities were offered to the farmers for its easy removal, more sludge could be disposed of. No charge is made.

21985. Does it contain any chemical poisons?—The sludge does not contain an appreciable amount of chemical poisons.

21986. Do you find any nuisance from the treatment of sewage in chemical precipitation tanks? Have any complaints been made?—No nuisance arises from the treatment of sewage in precipitation tanks; but arises from the mud drying in lagoons. No strong complaints have been made.

Mr. W. H. Harrison, M.Sc.

11 May 1905.

21987. As regards septic tanks, how should they be shaped ?—Septic tanks should be rectangular in shape and from 6 to 8 ft. deep. It is preferable to have the flow across the short width of the tank so as to reduce the rate of flow of the liquid as much as possible. The outlet should draw off below the water level so as to retain floating matter within the tank.

21988. Should they be used in series or in parallel ?—Septic tanks are best used in parallel so as to reduce the rate of flow of the liquid to a minimum. Tanks in series do not appear to possess any decided advantage over tanks in parallel, as used at Leeds, with the exception that the first tank in a series accumulates the heavier solids and may be, therefore, oftener cleaned out. In an experiment where four tanks, of 500,000 gallons capacity each, formed a series, it was found that the rate of flow through the first tank prevented septic action occurring, and as there was consequently no disturbance of the sludge, the latter accumulated so rapidly in the first tank that in a few months' time it was full of a very solid sludge.

21989. Should the septic tank be closed in, and, if so what advantages does a closed tank possess over an open one ?—Closed septic tanks do not possess any advantage over open tanks unless from the point of view of nuisance arising in densely populated districts, but even then the danger is only minimised. The effluents from both tanks are almost identical in composition. The averages of all analyses of effluents from Nos. 1, 2, and 3 open septic tanks and also effluents from covered septic tank from October 1899 to May 1904 were—

	Open Tank.	Closed Tank.
Ammoniacal Nitrogen - -	1·85	1·87
Albuminoid Nitrogen - -	·443	·418
Oxygen absorbed in 4 hours at 80° F. - - - -	6·10	5·48
Soluble Solids - - - -	89·4	88·1
Suspended S lids - - -	19·4	16·0

It is also found that the value of the roof in conserving the heat of the sewage is very small, for during cold weather the average loss in temperature in the open tanks was 1·6° F. and in the closed tanks ·8° F. The heating value of the collected gases is not great and their accumulation within the tank constitutes a serious source of danger. Briefly, I do not find any decided advantage arising from the use of covered tanks sufficient to justify the expenditure.

21990. What do you consider the best arrangement for the "feed" and "draw-off ?"—I do not attach great importance to the question of the best method of feeding the tank, for both the methods, feeding below and on the surface level, answer equally well. The outflow should, however, take place from below the surface.

21991. At what rate is sewage, as a matter of custom, passed through your septic tanks ?—At Leeds a 24 hour rate of flow has been adopted as the normal flow.

21992. What is the most advantageous rate of flow through septic tanks, and what is the rate of flow at which quicker passage through the tanks becomes, in your opinion, distinctly disadvantageous ? Why do you consider one rate more advantageous than another ? Do you think that the rate of flow should depend on the strength or character of the particular sewage which is being dealt with ?—The 24 hour rate of flow has been adopted as giving the best results, from the point of view of the amount of suspended matter in the effluent, with a minimum length of time within the tanks. It was found that even a 72 hour flow gave very little better results than a 24 hour flow, but that as the rate of flow was increased above the normal a larger proportion of suspended matter tended to come away from the tanks. I give an average of analyses showing the effect of different rates of flow through open septic tanks.

	12 hr. flow.	24 hr. flow.	48 hr. flow.
Ammoniacal N. -	1·65	1·76	1·82
Albuminoid N. -	·590	·409	·443
Oxygen absorbed 4 hrs. 80° F. - -	8·15	6·24	6·10
Soluble solids - -	97·7	95·3	96·7
Suspended solids -	28·0	16·4	15·5

These observations were made in 1899 and 1900 and during 1901 and 1902 they were extended to a comparison of a 24 hour and 72 hour flow, viz. :—

	24 hr.	72 hr.
Ammoniacal N. - - - -	2·17	2·10
Albuminiod N. - - - -	·453	·403
Oxygen absorbed 4 hrs. 80° F. -	6.45	5.12
Soluble solids - - -	90·1	91·4
Suspended solids - -	21·7	14·1

I believe that the rate of flow should depend upon the character of the suspended solids in the sewage dealt with.

21993. Is it possible to "over-septicise" a sewage ?—I have never found it possible to over-septicise sewage even with the 72 hour flow. In that case when the effluent was applied in a normal manner to filters, normal results were obtained.

21994. What is the amount of digestion in your septic tanks and how do you calculate this ? How far do you find that the digestion is affected by the atmospheric temperature ?—The average amount of digestion obtained in the Leeds septic tanks is about 30 per cent. of the sewage suspended solids. As an example I give the method of calculating the digestion from data derived from Nos. 1, 2 and 3 open septic tanks from 1903 to 1904 :—No. 1 tank contained 667 tons of sludge containing 14·2 per cent. solids = 94·7 tons of dry solids ; No. 2 tank contained 818 tons of sludge containing 14·2 per cent. solids = 116·1 tons of dry solid ; No. 3 tank contained 547 tons of sludge containing 16·2 per cent. solid = 88·6 tons dry solid *i.e.* from all the tanks combined there was obtained a total of 299·4 tons dry solids from which, deducting 15·3 tons of sludge use for inoculation purposes, and adding 1·49 tons for the dried scum removed from the tanks, is left 285·59 tons of undigested solids in the tank. The tanks were working 627 days exclusive of stoppages and in this period treated a total of 470,300,000 gallons of sewage containing an average of 33·2 grains of suspended matter per gallon. This gives a grand total of 995·9 tons of solids entering the tanks with the sewage. $\left(\frac{470,300,000 \times 33{\cdot}2}{7000 \times 2240}\right)$ The effluent carried away an average of 12.7 grains of suspended matter. Thus 381 tons of solids were carried away in the effluent. The undigested solids = solids present in the tank as sludge + solids carried away in the effluent = 381 + 285·59 = 666·59 tons *i.e.* 329·31 tons of solids have been digested giving a digestion of 33·0 per cent. I have no data bearing directly upon the effect of the atmospheric temperature upon the digestion : judging from the evolution of gas it must be considerable *e.g.* in a certain area of a small experimental tank, during August 1901, 37 litres of gas were daily collected, but in November 1901, only 13 litres were collected.

21995. Do you think a certain amount of sludge should be removed periodically from septic tanks or do you prefer to work them for a considerable period without cleaning and then remove all the sludge ?—A certain amount of sludge ought to be removed at periodic intervals in order to facilitate the treatment and disposal of the sludge. There is also a tendency for the sludge in the tanks to become consolidated, if left too long undisturbed, causing difficulty in the withdrawal of the sludge from the tank.

21996. How often would you clean out the tanks ?—The tanks at Leeds are generally cleaned out every two years but it would be preferable to do this say every eighteen months. If the tank is left uncleaned for too long a period the suspended solids in the effluent become excessive.

21997. Do you find that the suspended solids coming away with the tank liquors tend to increase in amount towards the end of the period of working, *i.e.* as the time approaches for removing sludge from the tanks ?—The

amount of suspended solids in the effluent, apart from occasional flushes of solids, does undoubtedly tend to increase as the sludge accumulates within the tank.

21998. What amounts of suspended solids are contained in your septic tank liquor at the commencement of the period of working the tank, just after the tank has been cleaned out, and at the end of period when the tank is thrown out of use for the purpose of cleaning out, and what is the average amount ?—From January to June 1903 with a perfectly clean tank the suspended solids averaged 12·2 parts per 100,000 and from July to December 1904 the effluent from this tank averaged 24·1 parts.

21999. With certain automatic gear the level of the liquid in a septic tank fluctuates. Have you made any observations for the purpose of determining whether such fluctuations disturb the proper working of the tank in any way, as, *e.g.*, by causing an increased amount of suspended solids to issue from the tank ?—The closed septic tank at Leeds is operated upon the principle of a fluctuating water level, and in no way has this affected the character of the effluent. Again, at one time in order to obtain a large bulk of liquid in a short period of time it was the practice to lower the water level of the open septic tanks from nine inches to one foot. This procedure had no effect the scum and suspended solids remaining normal.

22000. Do you find that septic tank liquor is more easily treated on filters than settled sewage or than precipitated sewage, assuming that in each case you have the same amount of suspended solids in your tank liquor ? —I have not found that septic tank effluent is more easily treated upon filters than settled or precipitated sewage. Two single contact beds, one treating septic tank effluent and the other precipitated sewage, gave the following average results :—

	Filtrate from Bed treating Septic Effluent.	Filtrate from Bed treating Lime Precipitated Sewage.
Ammoniacal N.	1·46	1·47
Albuminoid N.	·193	·193
Oxygen absorbed 4 hrs., 80° F.	1·51	1·45
Nitric nitrogen	·067	·077
Soluble solids	92·4	92·0
Suspended solids	9·5	6·4

These figures are the averages of all analyses extending over a period of two years. The septic tank effluent and the lime precipitation effluent contained approximately the same amount of suspended solids Septic tank effluent and settled sewage containing approximately the same amount of suspended solids gave the following average results when treated upon the same continuous filter. The septic tank effluent was used in 1903 and the settled sewage in 1904, the bed being washed out between the experiments :—

	Filtrate from Bed treating Septic Tank Effluent.		Filtrate from Bed treating Settled Sewage.	
	Unfiltered Effluent.	Filtered Effluent.	Unfiltered Effluent.	Filtered Effluent.
Ammoniacal N.	·408	·374	·295	·253
Albuminoid N.	·142	·076	·137	·070
Nitric nitrogen	·913	1·06	1·27	1·42
Oxygen absorbed 4 hrs., 80°F.	1·90	·734	1·61	·945
Dissolved oxygen taken up in 24 hrs.	35%	24%	32%	15%
Incubator test before	·59	·29	·58	·34
Incubator test after	·61	·32	·54	·31
Suspended solids	11·2	3·0	12·9	6·4

I am of opinion that septic tank effluent and precipitated or settled sewage, provided that the amount of suspended solids is approximately equal, give practically identical results when subjected to similar methods of treatment.

22001. Do you find any nuisance from the treatment of sewage in septic tanks ? Have any complaints been made ?—Very little, if any, nuisance arises from the open septic tanks at Leeds. This is probably due to the presence of iron in the sewage, which, under septic action, forms sulphides of iron in the tank and consequently the production of evil smelling organo-sulphur compounds is prevented to the extent of the production of iron sulphides.

Mr. W. H. Harrison, M.Sc.

11 May 1905.

22002. Is a scum necessary or desirable in septic tanks ?—One of the difficulties experienced at Leeds has been caused by heavy flushes of suspended matter from the tanks, whether open or closed. This has been traced to the breaking up of the scum and occurs chiefly during wet weather, and for the past two years it has been the custom at Leeds to keep the surface of the tanks free from scum. This has prevented, to a great extent the flushes of suspended matter from the tanks, and the absence of scum has not interfered in any way with the action of the septic tanks.

22003. Do you think it desirable that the suspended solids in sewage should be removed as far as practicable before sewage is filtered ? If so, what do you consider a practicable limit to get down to ?—It is comparatively easy to purify the liquid part of sewage, but the solids are much more difficult to oxidize to a stable form. The difficulty of treating any liquid effectively is proportionate to the amount of suspended matter present, hence the latter should be removed as far as practicable before filtration. With septic tanks, even with a seventy-two hours' flow, it is impossible at Leeds to reduce the suspended solids below an average of fourteen parts per 100,000. Precipitated sewage containing about 4·5–6 0 parts of suspended matter I find is very easily treated on filters, especially those of the continuous type.

22004. How do you consider that the removal of suspended solids can best be effected ?—In order to reduce the suspended solids as far as possible, precipitation with an efficient settlement area should be adopted. In some cases sedimentation without chemicals would answer.

22005. As regards contact beds, do you find that within certain limits the depth may vary without affecting the efficiency of the beds ? If so, what limits do you think are permissible ?—At Leeds, contact beds, varying in depth from three to six feet have at one time or another been used, and within these limits the primary and secondary beds having a depth of six feet gave somewhat better results than those of less depth. This difference I do not attach importance to, as differences in material, and the grading thereof, and the methods of working the beds might account for it.

22006. What do you consider the most convenient size for a contact bed ?—For large volumes of sewage I consider the most convenient size for a contact bed to be half-acre area.

22007. What do you find to be the best filtering materials ? What is the material (which can be had in practicable quantity) that, while efficient, is in your experience the least disintegrable in a contact bed ?—I have only had experience of destructor clinker and coke of various qualities, and of these I prefer hard furnace coke.

22008. What size should the filtering material be, and should it be graded in the beds ?—The size of the material used in contact beds should be as small as is conformable with other conditions, *e.g.*, if the liquid to be treated contains little or no suspended matter the material may be clinkers or coke-breeze with only the dust taken out, but otherwise the material for the primary bed should have a diameter of one inch or over, the secondary bed being made of much smaller material. Apart from covering the drainage with coarse material, and in certain cases the use of a very fine surface layer, I see no advantage in grading the bed material.

22009. Do you think it generally desirable that sewage should be subjected to some form of tank treatment before it is put on contact beds ?—Sewage, screened or grit settled, I consider, should not be applied to contact beds, owing to the very rapid loss of capacity which occurs. To minimise this loss of capacity it should be subjected to treatment having the primary object of reducing the amount of solids sent on to the bed ; incidentally better nitrated filtrates are produced.

22010. What periods of filling, standing full, emptying and standing empty do you consider best in practical working for primary beds and for secondary beds ?—The method of working the beds at Leeds is :—one hour to fill, two hours standing full, one hour to empty, and

Mr. W. H. Harrison, M.Sc.

11 May 1905.

four hours standing empty. This cycle is repeated every eight hours, both for primary and secondary bed. In order not to overwork certain filters it has been the practice to follow the above procedure for two eight-hour shifts and to rest the beds completely for the third shift. Longer periods of rest have been tried at Leeds. Thus No. 1 and 2 beds, from February 20th to March 18th. 1899, received two fillings per day with two hours contact and rested altogether on Sundays. Under these conditions a purification of 87 per cent. on the Alb. N. test was obtained. From March 21st to May 7th, 1899 they were worked in the same way, but were allowed to rest on Wednesdays and Sundays and gave a purification of 89 per cent. From May 7th to July 5th, 1899, they were allowed to rest alternate days, and gave a purification of 92 per cent. From July 5th to October 4 h, 1899, with one filling per day and two hours contact they gave a purification of 90 per cent. These facts point to an increased purification being obtained with increased periods of rest. Very little advantage, if any, is gained by increasing the hours of contact from two to four hours.

22011. How should contact beds be filled and emptied ?—Contact beds should be filled as quickly as possible, without disturbing the surface material and it is essential that the liquid should be distributed over the whole surface as evenly as possible. This has been attained after numerous experiments with movable troughs in various forms, by cutting grips in the surface material about three feet apart and connected together at intervals by cross channels. These grips are far more effective than troughs, etc., and any sludge which accumulates within them is easily removed. In emptying, the best method is to allow the liquid to flow away from the bed at an even rate, controlling the flow by means of valves.

22012. What are your views as regards automatic gear for filling and emptying contact beds ?—The only gear used at Leeds for automatically filling and discharging contact beds is the one supplied by the Exeter Septic Tank Syndicate. This is very complicated, but on the whole works very well. Owing, however, to the danger of the smaller tubular parts clogging it is necessary to give constant supervision. This apparatus regulates very well the time the liquid is in contact with the bed material, but it would not be an easy matter to readily alter this length of period if necessary. The chief objection to this apparatus lies in its inelasticity, for the daily routine having been fixed it would take some considerable time to alter the relationship of the various parts to suit another system of working. This gear does not take into account the fluctuations in the flow due to increases in volume, chiefly because of the fact that a bed is not filled until the one before it in the cycle has had its full period of rest and is emptying.

22013. What amount of tank liquor per cubic yard of filtering material can, in practice, be properly treated in a primary contact bed in twenty-four hours ?—The amount of tank liquor which a primary bed can treat per cubic yard of filtering material depends upon loss of capacity which has taken place since its construction. A primary contact bed when new and receiving three fillings per day of crude sewage, at Leeds, treated about 200 gallons per cubic yard per day, but at the end of two years would, at this rate of working, only treat about sixty-six gallons per cubic yard per day. Analytically the results were satisfactory throughout the whole period. Again, another bed, receiving two fillings per day of septic tank effluent and resting one week in every four, when new, treated an average of about 120 gallons per cubic yard per day ; but in March 1905, four years later, could only treat an average of about fifty-four gallons per cubic yard for twenty-four hours. This bed has treated on the average during the past two years about sixty-five gallons per cubic yard per day with really excellent results.

22014. What amount of liquid from a primary bed can in practice be properly treated on each cubic yard of filtering material of a secondary bed ?—It has been the practice at Leeds to treat liquid on secondary beds at the same rate per cubic yard as on the corresponding primary beds.

22015. Is one contact sufficient for the conversion of certain tank liquors into a satisfactory effluent ?—I have never been able to produce a satisfactory filtrate with a single contact bed. In the great majority of cases the filtrate has been putrescent and unsightly.

22016. At what rate or rates do primary and secondary contact beds lose their water-holding capacity, and to what causes is the loss of capacity due ?—The rate at which primary contact beds lose their capacity varies directly with the amount of suspended solids in the liquid treated, lessens with increased periods of rest and is greater in winter than in summer. Secondary beds as a rule retain a large percentage of their initial capacity.

The rate is in direct proportion to the suspended solids in the liquid treated.—A primary contact bed from October, 1897, to October, 1899, treated about 56,000,000 gallons of more or less crude sewage and in this period lost 56,500 gallons of the initial water capacity, *i.e.*, every 1,000,000 gallons of the sewage caused an average loss in capacity of about 1,000 gallons.

Another primary bed from July, 1901, to January, 1904, treated 106,000,000 gallons of septic tank effluent and lost 46,400 gallons of its original water capacity, *i.e.*, every 1,000,000 gallons of septic tank effluent treated produced an average loss in capacity of 437 gallons.

Again on the same primary bed with sewage which had been settled for one hour the rate of loss of capacity was 690 gallons per 1,000,000 treated ; with sewage which had been settled half an hour the rate was 820 gallons, and with sewage which had been settled a quarter of an hour the rate was 1,580 gallons. Screened sewage under the same working conditions reduced the capacity at the rate of 2,060 gallons.

The rate is in the inverse ratio to the amount of rest given to the beds.—A primary bed treating screened sewage at three fillings per day reduced the capacity at the rate of 1,750 gallons per 1,000,000 treated, and at two fillings per day at the rate of 680 gallons. This experiment was carried out in the spring of 1898.

In the early part of 1899 partially settled sewage at three fillings per day reduced the capacity at the rate of 2,000 gallons per 1,000,000 gallons treated. The same liquid at three fillings per day, but with the bed resting on Wednesdays and Sundays reduced the capacity at the rate of 1,300 gallons, and with three fillings per day but the beds resting on alternate days there was an increase in capacity at the rate of 1,500 gallons.

The rate is greater in winter than in summer.—I have taken as an example a bed treating septic tank effluent since 1901 under uniform conditions.

Year.	Rate of loss of capacity per million gallons, treated in	
	Winter (Dec. Jan. Feb.)	Summer (June July August)
1901	680	—
1902	280	160
1903	450	Nil
1904	750	440
Average	540	200

In order to show the way in which loss of capacity takes place I give the following capacity tests of a primary bed working under uniform conditions, the capacity of the empty bed being taken as 100, the actual figure being 178,000 gallons :—

Date.	Capacity with the 100 unit.	Actual galls.
1901 July 16 - -	48·8	86,900
September 27 -	44·4	79,100
November 22 -	42·8	76,200
December 20 -	44·4	79,100
1902 February 14 -	41·2	73,300
April 11 - -	39·5	70,300
June 6 - -	38·7	68,900
August 29 - -	37·9	67,400
October 24 - -	37·0	65,900
December 19 -	37·0	65,900

Date.	Capacity with the 100 unit.	Actual galls.
1903 February 13	35·9	64,000
April 9	34·8	62,000
June 5	33·7	60,000
August 1	33·7	60,000
October 23	33·3	59,400
December 18	31·6	56,200
1904 February 1	29·9	53,200
April 8	29·1	51,800
June 3	28·6	50,900
August 26	27·1	48,100
October 21	25·7	45,700
December 16	22·7	40,500
1905 February 10	20·5	36,600

This bed was receiving two fillings per day of septic tank effluent and was allowed to rest one week in every four, so that in no sense was it overworked. The analytical figures for septic tank effluent have already been given in answer to a previous question (21989). The bed received about forty-one fillings per month on the average.

Loss of capacity is due to the following causes :—

(1.) The passage of undigestible matters into the body of the filter.

(2.) The breaking down of the bed material.

(3.) The consolidation or packing together of the bed material.

(4.) The formation of a form of organic earthy matter akin to humus within the body of the filter.

(5.) The large amount of water retained in spongy deposit around the bed material.

22017. Can the material of a clogged bed be washed, and, if so, how can this best be done, and at what cost per cubic yard ?—The bed material may be readily washed and this I have done to the extent of 1,020 cubic yards by hand labour using screens and a heavy flow of water at a cost of 2s. 5d. per cubic yard. With the use of mechanical apparatus, the cost should be very considerably reduced. Washing is much more effective than turning over the bed material in regaining capacity. The latter method answers for the first time, but afterwards makes very little difference in the capacity.

22018. What is the average analysis of your single contact effluent ?—An average analysis of the filtrate from a single contact bed treating precipitated sewage gives : —

Ammoniacal N.	1·47
Albuminoid N.	·193
Nitric nitrogen	·077
Oxygen absorbed four hours at 80 °F.	1·45
Suspended Solids	6·4

An average of analyses of filtrate from a single contact bed treating open septic tank effluent gives :—

Ammoniacal N.	1·46
Albuminoid N.	·193
Nitric N.	·067
Oxygen absorbed four hours 80 °F.	1·51
Suspended Solids	9·5

An average analysis of filtrate from single contact beds constructed by the Septic Tank Syndicate and treating effluents from closed septic tank (October, 1899, to May, 1904) gives :

Ammoniacal N.	·849
Albuminoid N.	·161
Nitric N.	·695
Oxygen absorbed 4 hours 80° F.	1·09
Percentage of dissolved oxygen absorbed (1903 to 1904)	44
Suspended Solids	4·85

An average analysis of filtrate from double contact beds treating more or less screened sewage (November, 1898 to October, 1899) gave :

Ammoniacal N.	·374
Albuminoid N.	·095
Nitric N.	·560
Oxygen absorbed	·714
Suspended solids	2·71

An average analysis of filtrate from double contact beds treating septic tank effluent (1903 and 1904) gave :

Ammoniacal N.	·186
Albuminoid N.	·035
Nitric N.	2·07
Percentage of dissolved oxygen absorbed	16
Oxygen absorbed 4 hours 80° F.	·520
Suspended solids	heavy trace

22019. Do you find any chemical poisons in you final effluent ?—No chemical poisons are present in the effluents.

22020. What is the average amount of suspended matter in the primary bed effluent and in the secondary bed effluent ? Does most of this suspended matter come out with the first flush or not ?—The amount of suspended matter in the primary and secondary bed effluents varies with the amount of solids in the liquid treated. With more or less crude sewage, the primary bed gives an average of 16·3 and the secondary bed 2·71 parts of suspended matter per 100,000. With septic tank effluent the primary bed filtrates give an average of 10·4 parts per 100,000 and the secondary bed filtrates only a heavy trace. The greater portion of these suspended solids are found in the first flushes.

22021. Have you made any experiments which throw light upon the action of contact beds when full and when resting, or upon the conditions of aeration of contact beds ? —From a comparison of the results obtained from contact beds working under various conditions and treating liquids of various compositions, I hold the opinion that the action of these beds may be divided into two distinct headings, viz., (1) the oxidation of the solids and (2) the oxidation of the liquid impurity. When a bed is filled the solids during the period of resting full, settle out on the bed material, and the greater proportion of them are retained so as to gradually pass through the body of the filter during subsequent operations. These solids, and also any solids removed from solution, when the bed is resting empty are oxidised with the production of nitrates, etc., which in the following filling are dissipated throughout the body of the liquid. The liquid impurities are then oxidised, when the bed is full : (1) at the expense of any dissolved oxygen and (2) at the expense of the dissolved nitrates, etc., formed by the oxidation of the solids when the bed is resting empty. These liquid impurities are very easily oxidized and in many cases if it were practicable to remove the suspended solids from the primary bed filtrate the clear liquid would fall below the provisional standards. This heory accounts for the following facts :—(1) the effluent from a primary contact bed is devoid of dissolved oxygen, but contains more or less nitrates according to the length of time the bed rests empty. The soluble solids in the liquid in the first bed are very unstable and readily oxidised, hence the dissolved oxygen is soon used up, while the nitrates which then become available are destroyed in proportion to the length of time the bed stands full. Thus a single contact bed at Leeds receiving two hours contact and four hours rest gives a filtrate with no dissolved oxygen and only ·067 parts of nitric nitrogen, whilst a single contact bed receiving the same type of liquid, but only having one and a quarter hours contact and about twelve hours rest gives a filtrate containing no dissolved oxygen and ·695 parts of nitric nitrogen. This latter filtrate when saturated with air absorbed practically all the dissolved oxygen, while the former, containing less unoxidized dissolved impurity, absorbed less of this dissolved oxygen. (2) As the liquid impurities are oxidized when the bed is full at the expense of the dissolved oxygen and the nitrates present in the liquid it follows that a period of contact longer than is necessary to utilize this supply of oxygen is useless. This is borne out by experiment at Leeds ; for a four hours contact is no better than a two hours contact. (3) The filtrate from a secondary bed contains dissolved oxygen showing that the oxidation taking place in the first bed has been effective, and all the dissolved oxygen introduced into the liquid during its passage from the primary into the secondary bed has not been needed for further oxidation in the latter bed, the over-plus appearing in the final filtrate as " dissolved oxygen." It also follows that most of the nitrate formed in the secondary bed during its period of rest appear in the final filtrate. Hence the better oxidized a first bed effluent is the greater amount of dissolved oxygen and nitrate is found in the filtrate

Mr. W. H. Harrison, M.Sc.

11 May 1905.

from the second bed. This is borne out by experiment. The actual course of the oxidation of the two kinds of organic impurity is not so definitely divided as is given in the foregoing brief account, for part of the solids are oxidised when the bed is full and part of the retained liquid when the bed is empty. This is shown by the fact that the more solids a liquid contains the worse the quality of the filtrate. In this connection it must be remembered that even when the bed is resting empty the amount of air available is limited to about the capacity of the bed; hence with liquids containing large amounts of suspended matter there is always an over-plus left unoxidized during these periods of rest which use up the available oxygen and nitrate of the next filling, causing a surplus of unoxidized soluble solids in the filtrate, and necessarily deteriorting the quality of the secondary filtrate. Summarizing these conclusions the period of aeration should be as long as is practicable, the time of contact in primary beds should only be long enough to use up the available oxygen and nitrates, and the liquid to be treated should contain as few solids as possible.

22022. How can the capacity of contact beds be best maintained?—In order to maintain the capacity of contact beds at as high a figure as possible no solids should be sent on to the filter. Where this is impracticable good results have been obtained at Leeds by the use of septic tank effluent upon a primary bed constructed of fine material (clinker) of three-eighths to five-eighths inches diameter and covered with a surface layer of very fine coke breeze to a depth of six inches. By this means a larger proportion of the solids in the septic tank effluent are retained in the feeding grips and when dry are easily removed. Such a primary bed has been in use at Leeds for nearly four years, but notwithstanding these precautions the water capacity has been reduced during that period from 86,000 gallons to 36,000 gallons. The experience at Leeds has been that the material of contact beds will sooner or later have to be washed or renewed.

22023. As regards continuous or percolating filters, what do you find are the best filtering materials, and what size should the material be?—I find coke to be the best material as clinker breaks down very readily. Broken bricks or any material which is not liable to disintegration answers better than coke. The material should be of such a size that the solids can gradually pass through the filter and appear in the filtrate. Material of not less than three inches diameter is a useful size.

22024. What depth should a percolating bed be to obtain a good effluent?—The depth of the filter should vary according to the amount of solid in the liquid treated. Thus with screened sewage containing an average of about fifty seven parts of suspended matter, a bed from ten to twelve feet deep is needed. With septic tank effluent or settled sewage containing about fifteen to seventeen parts of suspended matter a bed from eight to ten feet is needed, and with a liquid containing only a small proportion of suspended matter, such as well precipitated sewage, a bed from five to six feet deep will answer.

22025. Do you think it generally desirable that sewage should be subjected to some form of tank treatment before it is put on percolating filters?—It is desirable to remove as much suspended matter as possible from the sewage (1) owing to the ease and rapidity with which a clarified liquid can be treated, and (2) the absence of a large amount of suspended matter in the filtrate, thus obviating the necessity for any after treatment of the filtrate to remove these solids.

22026. How should percolating filters be fed?—Liquids should be distributed over percolating filters in such a way that each unit of surface receives the same volume of liquid in a given time.

22027. Should the feed be intermittent or continuous?—The feed should, if possible, be continuous as any intermittency tends to produce a filtrate fluctuating in quality. This applies more especially to filters constructed of coarse material.

22028. What is the best form of distribution? What, in your opinion, are the conditions which have to be fulfilled by a perfect distributor, having regard not merely to the distribution of the liquid itself, but also to the purification of the liquid and the life of the bed?—The best form of distribution is by means of sprinklers. A sprinkler should be able to deliver liquid in a continuous stream on to the surface within wide limits of volume per unit area; it should rotate smoothly and easily and not be affected by wind pressure to any great extent; the exit holes on the rotating arms should be large enough to pass particles of growth, and it should be possible, with great ease, to clean the interior of the arms. The bearings of a sprinkler should be outside the flow of sewage and no alternating gear should be provided unless absolutely necessary. In that case, when the sewage flow is small, the arms come to rest during the period in which the sewage is accumulating. When the sewage is released a large volume passes through a very small portion of the filter, and this continues until the arms gain momentum. Tipping troughs, fixed troughs, and tray methods of distribution are all open to the objection that with rates of flow such as 200 gallons per square yard they are very liable to freeze in winter.

22029. Do you think it best to put on the filter a fairly constant amount of liquid, or do you consider that the amount can be increased in times of storm without impairing the efficiency of the filter or the quality of the effluent?—The rate of flow on to a filter can be increased in storm-times without causing any detriment to the filter. In the case of liquids free from suspended matters being treated, the rate of flow can be increased from 200 to 1,200 gallons per square yard with impunity.

22030. Is there any practical advantage in artificially heating the liquid which is being treated on percolating filters?—There is no practical utility in heating the liquid sent on to precolating filters. Filters unheated in any respect give at Leeds filtrates which in winter are non-putrescent and generally well below the provisional standard.

22031. Have you had any experience to show whether open sides are an advantage to a percolating filter?—A comparison of the filtrates from various types of filters shows that side æration is not necessary. A filter at Leeds constructed without side æration gave fully ærated and well-oxidized filtrates. In this case the bottom of the filter was well ærated.

22032. Have you made any study of the conditions of æration of percolating filters, and is it desirable that the bottom of the filter should be raised from the ground?—A study of the conditions of æration has shown that to maintain the efficiency of a filter it is essential that there must be a free admission of air to the base of the filter and that the top surface must be kept free from growth so that no ponding occurs. It is, therefore, desirable that the base of the filter should be above ground level.

22033. What do you consider the most convenient superficial area for a percolating filter?—For large volumes of sewage, filters having a diameter of from 100 to 150 feet would seem to be desirable.

22034. Do percolating beds, in your experience, choke? If so, have you been able to measure the rate of choking, and how do you suggest that this choking can be removed and at what cost?—Filters constructed with material which is liable to disintegrate or which is too fine, do readily choke. Thus a filter constructed of clinker having a diameter of three-eighths to five-eighths inch became useless at the end of two years, whilst a filter constructed of coke having a diameter of two and a half inches and upwards is still giving satisfactory results after a working period of six years. Both of these filters were treating septic tank effluent. A filter constructed of slabs of clinker each about one foot across and packed vertically by hand became useless in less than two years owing to the disintegration which had taken place. The only effective way to prevent choking is to use a hard material, which does not easily wear, and in pieces over three inches diameter. In this case, any solids which accumulate may be largely washed out by means of large volumes of water. The heavy flow through such a filter when storm waters are treated also tends to keep it free.

22035. Of what nature are the suspended solids in the filter effluent?—How much is organic matter, and are they putrescible apart from the liquid portion of the

effluent ?—An analysis of the chief constituents of the sludge deposited from a continuous filter effluent is :—

	per cent.
Loss on ignition	40·4
Sand and insoluble matter	18·9
Oxides of iron and alumina	31·3

This sludge is usually non-putrescent.

22036. Have you any experience of, or any suggestions to make on, the settlement or other separation of the suspended solids issuing from a percolating filter, and to what minimum figure do you think such settlement or other final treatment can be carried as a *practical* measure ?—Solids in these filtrates are readily settled out as they are heavy and granular in appearance, but a better and more effective method is by mechanical filtration. The filters are constructed of fine furnace ashes and have a depth of six inches, with side walls rising about two feet above the surface of the ashes, so that the liquid to be filtered can pond up to that depth. The whole is underdrained by means of agricultural tiles. In practice the filter effluent is run on to the surface at the rate of 400 gallons per square yard, and percolating through the material becomes freed from suspended solids. Such a filter will continue to treat a filtrate containing about eleven parts per 100,000 of solids for a period of about one month before it becomes necessary to stop the flow on to it. The filtered solids soon drain dry and splitting up into small cubes are easily scraped from the surface, the filter being then ready for use again. In practice it is possible to produce a result containing from four to five parts per 100,000 of solids.

22037. Do you find that the suspended solids in your filter effluent vary very much in amount from time to time, and, if so, can you explain the causes of such variation ?—The solids in the filter effluent vary very greatly in amount, the largest quantity appearing in spring and autumn. Generally speaking there are more solids present during the warmer months of the year, and the fluctuations are more pronounced with a comparatively new filter. It is usually found that after one of these periods of flushing out of solids that the suspended matter present in the filtrate shows a diminution in quantity. The average amounts of suspended matter per month in the filtrate from a bed treating septic tank effluent were :—

Mr. W. H. Harrison, M.Sc.

11 May 1905.

Month.	1902	1903
January	11·1	8·9
February	19·8	1·4
March	19·8	9·5
April	10·4	8·7
May	2·7	10·4
June	1·7	16·4
July	13·0	5·0
August	10·2	12·8
September	6·0	10·4
October	7·8	15·2
November	8·2	12·5
December	4·1	12·2

These flushes would appear to coincide with the activity of the higher forms of life within the filter.

22038. What was the cost of your percolating bed installation per acre, and how much liquid do you treat per acre per twenty-four hours, at ordinary times and in storm times ? Please give the depth of the filter and an average analysis of the liquid which you put on, and an average analysis of the effluent when working at the ordinary rate and when working at a greater rate in storm times ?—As all the various filters at Leeds have only been experimental no reliable figures can be given, but the cost, calculated per acre, for continuous filters from nine to ten feet deep has been about £9,000 to £13,000 per acre, according to the manner of construction. In ordinary times the usual amount treated is 200 gallons per square yard per twenty-four hours, rising in times of storm to 1,200 gallons per square yard. The following are the average analyses :—

I. Filter treating Septic Tank Effluent and having a depth of 9 ft. 6 in. of Bed Material (1903).

	Septic Tank Effluent.	Bed Filtrate.	
		Unsettled.	Sand Filtered.
Ammoniacal N.	1·05	·403	·374
Albuminoid N.	·363	·142	·076
Nitric N.	—	·993	1·06
Oxygen absorbed 4 hrs., 80 °F.	5·96	1·09	·734
Incubator Test before	—	·59	·29
Incubator Test after	—	·61	·32
Dissolved Oxygen absorbed in 24 hours	—	35 per cent.	24 per cent.
Suspended Solids	15·9	11·2	3 0

No storm waters were treated on this filter.

Mr. W. H. Harrison, M.Sc.

11 May 1905.

II. Filter treating Settled Sewage and having a depth of 9 ft. 6 in. (1904).

	Settled Sewage.	Bed Filtrate.	
		Unsettled.	Sand Filtered.
Ammoniacal N.	1·73	·295	·253

Mr. W. H. Harrison, M.Sc.

11 May 1905.

22039. Have you observed the effect of changes of atmospheric temperature on the working of a percolating filter ?—I hand in a Table showing the average maximum and minimum temperatures for each month from July, 1904 to February, 1905, and also the variations in the percentage of purification. The filter was treating precipitated sewage, and consequently the filtrate contained very little suspended matter. I have chosen this example owing to this fact, for when solids are present in quantity in a filtrate the changes in purification due to changes of temperature are masked by the fluctuations in the suspended matter :—

Month	Temp. °F.		Precipitated Sewage.				Filtrate.						Percentage purification in Alb. NH_3.
	Min.	Max.	Amm. N.	Alb. N.	O. Abs.	Suspd. solids.	Amm. N.	Alb. N.	Nitrn. N.	O. Abs.	Percentage of dissolved O. absorbed.	Suspd. solids.

Feb. ,,	35	45	1·88	·420	3.52	5·2	·438	·084	1·30	·480	5	1·0	80·0

Generally speaking these figures show that the purification is affected by changes of temperature for (1) the amount of ammoniacal nitrogen in the filtrate approximately increases with a decreasing temperature; (2) the purification in albuminoid nitrogen and the oxygen absorbed value decreases approximately with a decreasing temperature.

22040. Have you found any trouble from vegetable growths in percolating filters ?—Growths appear in quantity upon the surface of the continuous filters at Leeds in the early and later periods of the year when it is necessary to repeatedly fork the surface in order to prevent ponding of the liquid, and so keep the interior of the bed well ærated. These periods only last from two to three weeks, and during the remaining portion of the year it is not necessary (or, at least only very occasionally) to fork the surface. These growths are the same as are found upon the walls of the main sewers, and the fact that they only grow readily at particular periods upon the filters would seem to point to the sewage temperature, which is intermediate at these times, being the determining factor in their rate of growth or else in their season of sporing.

22041. Would you kindly compare the cost (initial expenditure and annual cost of upkeep and working) and relative advantages of percolating filters and contact beds. Do you consider that one form is best for some kinds of sewage, and the other form for other kinds of sewage ?—The relative advantages of percolating and contact beds are : (1) If solids are present in the liquid to be treated, a greater depth of filtering material is required for percolating filters than for contact beds. If no solids are present, the difference is not great. (2) Percolating filters cost more to construct than contact beds. (3) If solids are present in the liquid to be treated, they are present in the effluent from percolating beds, necessitating extra settlement or filtration. Contact bed filtrates are practically free from suspended solids. (4) As a general rule, the filtrate from a continuous filter contains more dissolved oxygen than that from a contact bed. (5) The amount of liquid treated per cubic yard per day on contact beds is limited by the number of fillings which can be given, and decreases in amount as the beds lose capacity. With percolating filters the amount treated is constant, and if the bed material is coarse and not easily disintegrated by weathering influences, this amount remains constant for many years. Accumulation of solids within the body of a contact bed produces in time a great loss in the water capacity, which can be effectively regained only by washing the bed material. With coarse percolating filters these accumulations may, in the course of time, produce bad internal distribution, but this is easily remedied by turning a large volume of water on to the filter and flushing out the retained solids. Generally speaking, the effective life of a percolating filter will be longer than that of a contact bed. (6) Contact beds are less readily affected by changes in atmospheric temperature than percolating beds.

22041*. Do you find that the chance of nuisance is any greater with one form of filter than with another ? Does the risk of nuisance depend on the kind of sewage which is being treated or on the nature of the preliminary treatment to which the sewage has been subjected ?—I have never found that the actual filtering operations cause nuisance. The risk of nuisance arising, in my opinion, depends upon the nature of the preliminary treatment and the method of distribution, *e.g.*, the process of distributing septic tank effluent upon filters by means of spraying devices may give rise to nuisance.

22042. Have you made any comparative observations which show how many gallons per cubic yard per twenty-four hours of your tank liquor or tank liquors, could be satisfactorily purified on a percolating filter, and how many gallons per cubic yard on contact beds ?—I have treated various liquids upon percolating filters at the following rates per cubic yard per twenty-four hours, with the production in each case of a good filtrate :—(1) crude sewage on a twelve feet bed at the rate of forty-two gallons per cubic yard; (2) septic tank effluent on a nine feet six inch bed at the rate of fifty-three gallons per cubic yard; (3) settled sewage on a nine feet six inch bed at the rate of sixty-one gallons per cubic yard; (4) precipitated sewage on a six feet filter at the rate of forty-eight gallons per cubic yard; (5) precipitated sewage on a six feet filter at the rate of 100 gallons per cubic yard.

With regard to contact beds, in order to produce a good result it has been necessary at Leeds to adopt double contact in every case; therefore, to obtain the amount of sewage treated per cubic yard under these circumstances, the total number of cubic yards in the primary and secondary beds must be taken :—(1) crude sewage treated by double contact at three fillings per day on three feet filters gave a rate of 128 gallons per cubic yard per twenty-four hours at the commencement of the

* 1st filtrates from a new filter and therefore cannot be compared with others.

experiment. At the end of two years the amount which could be treated under the above conditions was only twenty-nine gallons per cubic yard per day; (2) septic tank effluent treated by double contact on six feet beds, receiving two fillings per day and one weeks' rest in every four, gave an average rate for 1903 and 1904 of thirty-three gallons per cubic yard per day, the maximum amount being forty-two gallons. Generally the average amount treated per cubic yard per day throughout the life of a filter is greater on a percolating bed than on a contact bed; analytical figures are given in answer to previous questions.

22043. What, in your opinion, constitutes a good effluent? I consider that a satisfactory effluent must conform to the following conditions:—(1) it must be non-putrescible; (2) the free ammonia value must be low and the nitric nitrogen value high; (3) the suspended matter must be low.

22044. What are your views of the various tests used in judging of the quality of an effluent, and of the advisability of a standard or series of standards?—I am not in favour of fixed standards of purity based upon limiting numerical values such as the present Mersey & Irwell standard, for the reason that different bacteriological processes produce effluents, even when the same liquid is treated, containing varying amounts of organic impurity, as determined by the usual tests, the quantity of which is no safe criterion of the power an effluent possesses of resisting putrefactive changes. Thus with the "oxygen absorbed in four hours" test the highest value I have obtained with a non-putrescent double-contact bed effluent has been 1·62 parts per 100,000. Above that figure the effluents have invariably been putrescent. On the other hand a continuous filter, treating crude sewage, gave effluents having a value as high as 2·30 which were non-putrescent. An effluent which at one time is non-putrescent with a given "oxygen-absorbed" figure is sometimes found to be putrescent when giving a much lower figure. In the case of the "Putrescibility of an effluent as measured by the Incubator test," I find that, even with the addition of urea to decompose nitrites, the "three minutes oxgyen absorption" figures are unreliable, many effluents giving higher values after incubation than before, although remaining perfectly sweet. In all cases, however, where an effluent has really putrefied upon incubation, I have found that the "æration test" has also shown it to be putrescent, but when the effluent has remained perfectly sweet, although there has been an increase in the oxygen value of the incubator test, the "æration" test has shown it to be non-putrescent. I find that the most reliable method of determining the putrescibility of an effluent is by the "æration test." A really good effluent will not absorb more than 25 per cent. of its dissolved oxygen and a moderate effluent from 30 to 40 per cent. Above 50 per cent. all effluents which I have examined have been putrescent; any absorbing from 40 to 50 per cent. are doubtful in character. The free ammonia test is also very useful, for generally any effluent containing only a small quantity will be stable with regard to the "æration test." I regard the "oxygen absorbed" and the albuminoid ammonia tests as giving very parallel results with any particular sewage, and therefore, I do not consider it necessary to always determine both values. With regard to the amount of suspended matter in the effluent, I consider that a contact bed effluent should not contain more than three grains per gallon (4·2 parts per 100,000), and that a continuous filter effluent may contain up to five to six parts per 100,000, if the other tests are satisfactory, as the solids in this case are usually better oxidized than in the former.

22045. With regard to your answer to Question 21993, we have it from several witnesses that it is possible to oversepticise the sewage. You tell us that you have never found it so. Have you made several experiments?—Yes, but only in the general course of experimenting. I never tried it on contact beds. It may be possible there to oversepticise but I never found it so on continuous filters.

22046. (*Colonel Harding.*) You have in fact tried experiments for a considerable period with septic tanks at so slow a flow as would fill the tank in 72 hours, have you not?—Yes.

22047. And you did not find any material difference either in the effluent or in the evolution of evil-smelling gases?—No; it was practically a normal tank.

22048. (*Mr. Power.*) Are you disposed to think that the character of the trade effluent in your sewage has to do with the behaviour of the septic tank?—It may, for instance, be possibly owing to the larger amount of iron, which unites very rapidly with the large amount of sulphur in the sewage.

22049. (*Colonel Harding.*) You have not found that by largely reducing the flow there was a development of sulphuretted hydrogen?—In the gases given off?

22050. Yes?—No.

22051. (*Chairman.*) As far as you are concerned at Leeds, you think the septic tank might remain full for a week and the effluent would be just as easy to treat?—In one particular case—a good while ago now—we allowed a tank to stand for a month and began working it straight away on the contact beds and we found no difference at all.

22052. You found no difference?—No.

22053. After standing for a month you found no difference?—Of course, the tank became much more septic in condition.

22054. In your answer to Question 22000, there is a considerable difference with regard to the suspended solids —9·5 and 6·4?—That is probably due to the smaller amount of suspended matter going on with the lime effluent.

22055. Then with regard to Question 22018, the last analysis there is considerably better than the third analysis, is it not?—Yes, that is so.

22056. Have you any explanation of that?—Oh, yes, in the first case the beds received three fillings per day, but in the last case they received on the average only about $1\frac{5}{8}$ fillings a day. There was a much longer period of rest.

22057. Then on Question 22032. Have you found by actual experience that a filter with its base on the ground level would give worse results?—No. At Rodley we have a filter with its base actually under the ground level and simply aerated by vertical pipes down to the base, and in that case we get perfectly aerated results.

22058. In answer to Question 22032, you say it is desirable that the base should be above the ground level?—Quite so. If it is below the ground level there may be a danger of the access of air being easily stopped.

22059. But you have no actual experience of a filter with its base on the ground level having the access of air stopped?—No.

22060. (*Colonel Harding*). In speaking about the bottom of the filter being raised from the ground I think you mean that the material would be raised from the bottom of the filter. I do not think you mean to suggest that a percolating filter sunk into the ground would necessarily not be aerated if the same conditions applied?—No. I simply meant that there must be a given air space between the base of the material and the concrete floor.

22061. Such access might exist equally if the concrete was sunk into the ground?—Yes, we have it at Rodley.

22062. (*Chairman.*) In answer to Question 22036, you say that in practice it is possible to produce a result containing from four to five parts per 100,000 of solids. Have you any figures which would show the cost of that final treatment?—I have not with me, but I believe I gave some information to Mr. Willis some time ago.

22063. In reply to Question 22041, you state that percolating filters cost more to construct than contact beds. I suppose you are quite sure about that statement?—I think I am.

22064. Could you prove it by your own experience?—Only by the small experimental filters. It is the greater depth and the need for giving efficient aeration all round which causes the extra cost.

22065. (*Sir William Ramsay.*) Are you basing your experience on the Whittaker filters?—On most of the continuous filters.

22066. (*Chairman.*) In your opinion is the type of effluent from the contact beds superior or inferior to that from the percolating filter?—There is very little difference between the two effluents under the best conditions, but taken under the worst conditions—that is both beds

Mr. W. H. Harrison, M.Sc.

11 May 1905.

treating crude sewage—and with settlement of the effluent from the continuous filter, then I have no hesitation in saying that the continuous filter effluent is much the better.

22067. (*Mr. Power.*) There are one or two points I should like to ask you about, though I am afraid they may prove to be rather engineering matters than appertaining to your department. They have reference to the storm waters. I should like to understand this a little more clearly. Your dry weather flow is 17,000,000 gallons ?—Yes.

22068. And one-third of that will be trade refuse ?—Yes.

22069. Then as to soil water you say that may on occasion amount to 3,000,000 gallons per day ?—Yes.

22070. Then that does not leave you a great deal for domestic sewage under present conditions ?—I mean that 3,000,000 to be added on to the 17,000,000.

22071. You do ; it is not included ?—17,000,000 I put down as the dry weather flow ; these 3,000,000 only come in after periods of rain.

22072. Mainly in the winter time ?—Well, if it is a wet summer we get it then ; it is a dilution which only occurs after periods of rain.

22073. The next point was Question 21959,—that the maximum capacity of the sewer is 60,000,000 gallons ?—Yes.

22074. Well, that is not six times ; not quite four, having regard to the seventeen plus three ; that is a good deal short of six times the dry weather flow ?—That is so.

22075. Does that mean that the capacity of the sewers will not bring you down more than 60,000,000 a day ?—They will not under the constructional conditions.

22076. One tenth of an inch of rainfall per hour in twenty-four hours will give you that continuously,—the whole 60,000,000 in a day, will it not ?—Oh, yes, we very often get the sewer full.

22077. Then how about the overflows ; are there a number of overflows in the town, and at what points do they act ?—They are along the whole line of the sewers ; of the main sewers.

22078. And would they come into operation before the rate of six times the dry weather flow was reached ; I suppose they would ?—Yes.

22079. Then in time of storm there would be a good deal of polluting liquid going into the river that never comes near the works ?—By means of the storm overflow.

22080. Therefore what you say at Question 21972, as to treating six volumes of storm water means that you are prepared to do that by your process if it is delivered to you to do ?—That is so.

22081. And as a matter of fact you have now and again treated six times the customary amount by those very filters, I suppose ?—That is so.

22082. On Question 21972 still, three volumes in the ordinary way ; that would be three volumes of precipitated sewage, would it ?—Yes.

22083. At the rate of 100 gallons per square yard ?—Yes.

22084. Then you deal with the balance ; the other three you say "well settled ;" is that simply settled by subsidence tanks, and if so, for how long. In the lower part of Question 21972 you say : "I think the case would be fully met by treating three volumes as in the ordinary way, the remaining three volumes being well settled or precipitated"—and then you propose to treat that additional three volumes from 600 to 1,200 gallons per square yard ?—I mean there, really three volumes by the ordinary method of treating sewage water, by precipitation or whatever method of filtration.

22085. It would be at the rate of 100 gallons per square yard, the normal rate ?—Yes, 300 gallons.

22086. I want to know what you do with the balance you spoke of as being well settled ; is it in subsidence tanks, and if so for how long ?—It is about a four hours settlement for the storm water sewage.

22087. Would that require a very large instalment of tanks to deal in that way with the whole of the storm sewage of Leeds ; it would be on rather a big scale, would it not, four hours settlement. You see, it would be more than 60,000,000 gallons coming down when the sewers are enlarged, and the middens are converted into water closets ?—Oh, that is so, but I think if you add a little more precipitant you can do it with a 12-hour tank.

22088. You would use precipitant ?—I am using, here, only a little.

22089. Well settled or precipitated ; would you use some precipitant with it ?—Yes ; I was saying if you use precipitant you would treat the whole six times in the tank, which at normal times was a 12-hour flow—that is half 24-hour septic tanks.

22090. (*Sir William Ramsay*). Giving it 4-hour periods ?—Oh no, it would be two in that case.

22091. (*Mr. Power.*) And when you are treating this storm sewage at the rate of 600 to 1,200 gallons per square yard ; I see you have got out some very favourable figures ; are those effluents non-putrescent, generally ?—Quite non-putrescent.

22092. They are ?—Yes. I must say that I have been surprised myself at the character of the results I have obtained by this experiment.

22093. The bed is in no way damaged by running it to the extent of 1,200 gallons per square yard, for the best part of a day ?—I have had it going for two days without hurting the filters.

22094. Continuously ?—Yes.

22095. Without any damage to the subsequent filtrating ?—None that I could determine.

22096. (*Sir William Ramsay.*) Is there much subsoil water in the Leeds sewage ? In your answer to Question 21960 you have a very high maximum ; is that subsoil water ?—That is subsoil water, but it only occurs after long periods of rain.

22097. I suppose the septic tank liquor contains a quantity of iron in solution, or colloidal solution ?—It does.

22098. That has to be decomposed by the sulphuretted hydrogen, or rather there will be a double decomposition ; the albuminoid bodies will decompose and give sulphuretted hydrogen. Will that attack the iron and form a sulphide of iron ? I think you said, in answer to some other question, in no case have you had a smell of sulphuretted hydrogen ?—Not in the tank.

22099. That means that there is more iron than is sufficient to deal with it all ?—I have iron in solution in the septic tank effluent.

22100. However long it has been running ?—Yes.

22101. So that Leeds stands in a peculiar position as regards the nuisance likely to be caused by the septic tank. You will never have sulphuretted hydrogen ?—Oh, I think we stand in a very favourable position from that cause.

22102. In answer to Question 21964 you say that the suspended solids are more or less dark brown in colour ; have you estimated the inorganic matter in the solids ?—Is that from the ordinary sewage solids ?

22103. Yes ?—Roughly speaking, there will be about 50 per cent.

22104. Half of each ?—Yes.

22105. In the answer to Question 21965 you give oxygen absorbed in four hours, 10·8 : is much of that due to ferrous iron ?—Yes, there is some ferrous iron in the sewage.

22106. Can you give any information as to how much of the 10·8 is due to ferrous iron ?—I cannot, because the bulk of the iron enters the sewage in its ferrous state, but during its passage down to the works it becomes oxidised to some extent, and that varies very largely.

22107. In reply to Question 21972 you speak of a specially constructed storm water filter ?—Yes.

22108. You do not give any details as regards its construction ; what sort of filter was it ?—It is simply built on the usual contact-bed form.

22109. (*Colonel Harding.*) Is it on the lines suggested by the Local Government Board ?—As far as I understand them, it is.

22110. (*Mr. Power.*) What depth ?—Three feet.

22111. (*Sir William Ramsay.*) Is it filled ?—Yes.

22112. How does it work ?—We close the valves—the outlet valves—and run the storm water into it till the bed is full to the surface ; we then open the outlet valve to such an extent as to deliver the same volume of water that is going on to the filters.

22113. And you really use it as a continuous filter ?—A streaming filter, yes.

22114. In your answer to Question 21975c you describe the method of separating the sludge ; what becomes of the water that drains off the sludge ?—It drains back into the tanks.

22115. Some evaporates, I presume ; not much evaporates ?—Well, it can only do so from the top surfaces ; the top surfaces of the sludge very quickly become hard, but even when the top layer is sufficiently hard to walk across, the sludge beneath is quite wet.

22116. Then that must dry by evaporation ?—The top layer.

22117. And ultimately the under layer ?—It takes a long time.

22118. (*Colonel Harding.*) Does it take many years ?—To dry it by evaporation, I am afraid it would. I have tried it in small lagoons, just drying by evaporation, and even there, where the layer was a foot thick, it took several months.

22119. (*Sir William Ramsay.*) I remember you used to spread the sludge in thin layers in some way or other over a considerable surface of ground, and then, I think, it dried ; is not that so ?—If you can spread the sludge in thin layers, say six inches thick to begin with, it very quickly dries, then cakes ; as the water evaporates from the surface layer, the sludge at Leeds has a tendency to crack somewhat into cubes, so that air gets practically through the whole mass in time.

22120. Is the soil at Leeds sufficiently porous to make it possible to hope that the soil would act as a kind of filter, and a lot of water would get into the soil ?—I am afraid it would only answer once ; the soil would become clogged up.

22121. With the sludge ?—As a matter of fact we have to put a fresh layer of clinker at the bottom of the lagoon after clearing it out.

22122. In your answer to Question 21978, you say: "Recent experiments at Leeds have shown that an effluent produced by using eight grains of lime per gallon and two grains of sulphate of alumina, and practically free from suspended matter, can be treated more easily than septic tank effluent or settled sewage upon trickling filters" ?—Yes.

22123. That is not everyone's opinion ; I think we have had contradictory evidence to that ?—Well, as you see from the analyses, the results are well below the Rivers Board's standards.

22124. Yes ?—In both cases. In the one case where a septic tank effluent is treated on the filter, you get 10·5 parts of suspended solids in the effluent. Of course that necessitates a further process for draining off those solids. In the other case, where precipitated sewage is sent on to the filter, practically no solids appear in the effluent. Again, the gallons treated per cube yard are in the case of septic tank effluent 61 gallons ; in the case of precipitated sewage, 100 gallons.

22125. You do not mention the details of the septic tank liquor there at all ?—No, I have given them in another place.

22126. Is it the same liquor as you mention in answer to Question 22000 ?—Yes.

22127. That is the same liquor ?—Practically the same composition, yes.

22128. It might be advisable to refer to Question 22000 there ?—No, that is the filtrate from a bed treating septic tank effluent.

22129. Septic tank liquor that goes on ?—Septic tank liquor. I give it in the part dealing with septic tanks.

22130. (*Mr. Power.*) Is it not under Question 21992 ?—You get there the analyses for several rates of flow.

22131. Different flows ?—Yes.

22132. (*Sir William Ramsay.*) Would it not be well, in answer to Question 21978, to give the figures for the liquor ?—You get it at Question 21989.

22133. Then we might put a note to Question 21978 to say that this liquor is alluded to in the answer to Question 21989 ?—Yes, the open tank.

22134. In your answer to Question 21979 you say, "The most effective precipitant was a mixture of ferric salts and lime, closely followed in order of merit by aluminium sulphate and lime." What is the theory of those precipitants, ferric salts and lime ? Is it merely enclosure by the precipitated ferric oxide of the albuminoid matter ?—I take it so.

22135. That is all ?—I think so.

22136. Is oxidation that goes on due to ferric salts, do you think ?—I have not noticed any.

22137. Because it is rather unusual ?—The ferric salts ?

22138. No, that the most effective precipitant should be that ?—Well, what I mean is that it clears the liqiud in the shortest time.

22139. Well, naturally ?—There is very little difference between it and aluminium sulphate and lime.

22140. In answer to Question 21985, you say that the sludge does not contain an appreciable amount of chemical poisons. May I ask what you tested for. You mentioned an enormous quantity of arsenic coming into the sewage ; did you test for that ?—Yes, it is very small when mixed with the whole bulk of the sludge.

22141. Was there anything noticed as regards the clogging of the beds to which you refer in your answer to Question 22000 dealing with the single contact beds ; did the bed treating septic effluent clog more or less rapidly than the bed treating lime and sewage ?—No, the clogging in both of these beds was rather peculiar. After working several months, they lost a large part of their capacity ; I can give you the figures in a moment. The bed treating lime precipitated sewage had an original water capacity of 55,000 gallons. That was in March, 1899, and by October 20th of the same year the capacity had dropped to 21,000.

22142. What about the other ?—In the other case we started in March with 29,000 and dropped to 10,000.

22143. (*Mr. Power.*) In six months ?—By the end of September in that case.

22144. (*Sir William Ramsay.*) Practically the same period of time ?—Now in both of those cases the beds were rested, and the whole of the material was turned over, and in the first case the capacity rose from 21,000 it was in October to 53,000, very nearly the same as the original water capacity.

22145. What about the other one ?—The other one rose from 10,000 to 26,000 ; that was within 3,000 of the original water capacity. Considering the beds had had so little suspended matter on, we concluded that the loss of capacity was due to the material consolidating together.

22146. We have been told by one witness that it is a comparatively inexpensive matter to renew these beds by taking off the old material, rejecting the smaller portion, washing it and putting it back. We got exactly contradictory evidence from another witness, saying it is far too expensive an operation to be contemplated. Which is right ?—Well, if we use destructor clinker, which we can get for nothing, and put it in our contact beds, it would cost us to get into the bed between 4s. and 5s. a cube yard. If we renew that material say every four or five years the annual cost is going to be something enormous. If we wash it, we shall certainly lose a great bulk of the material. And then in addition to the cost of washing, which will probably be about 1s. 6d. to 2s. a cube yard, we shall have to replace the material washed away at a further cost of 5s. per cube yard.

22147. Then which would you regard as the more practicable ; is it necessary to replace the beds after four or five years working ?—It is necessary to do something to them. If you turn the material over you will get an increase of capacity, but the next time you turn it over, a few years later, you will not get such a large increase of capacity—in fact with one or two beds at Leeds we got a very small increase of capacity, so that once turned over you will either have to take the material out and renew it, or else wash it ; there is no other course open.

Mr. W. H. Harrison, M.Sc.

11 May 1905.

22148. Comparing these contact beds with continuous filtration, is it necessary to replace your continuous filters in the same way?—If your material disintegrates it is.

22149. Is there as much disintegration in the one case as in the other ?—I think it does occur in the case of a continuous filter.

22150. The disintegration is greater in the continuous filter ?—Well, I will not say it is greater, but the effect of it shows in a much shorter period of time.

22151. But would it be necessary to wash out a continuous filter, or add to the top ?—I am afraid not ; the whole objective of the filter should be to keep the liquor equally distributed throughout the whole filter ; if you have disintegration or consolidation you will get watercourses through the filter, which would produce a bad effluent.

22152. Without washing the substance ?—If you screened off the fine, broken-down material, I think it would do.

22153. That would be cheaper than replacing a contact bed I presume ?—I could not say.

22154. How do you keep the surface of the tanks free from scum ?—We allow the scum to form in the first instance. When we have got a continuous layer, we cut out a strip along the side of the tank in the direction to which the prevailing wind is blowing. We remove that strip by hand, and the wind carries the bulk of the scum to the side again. Then we cut off further strips till we clear the tank.

22155. In answer to question 22016 you say, "The rate at which primary contact beds lose their capacity varies directly with the amount of suspended solids in the liquid treated." Have you worked this out from the suspended solids going on during the period ?—Perhaps I should not say direct proportion, but it is in proportion to the suspended solids treated.

22156. That is to say that it is not a numerical proportion ?—Oh no, I did not intend it to mean that at all.

22157. And again, in this other answer in italics : "The rate is in the inverse ratio to the amount of rest" ? —The same applies.

22158. The same applies ; it is a general statement ?—I only meant it for a general statement.

22159. It is not intended to be numerically accurate ? —No.

22160. I wish to refer to your answer to Question 22021. I suppose you would imagine that oxygen gets into a contact bed from above during the period of rest ? —Resting full or empty ?

22161. Empty ?—Only by diffusion.

22162. Do you imagine that it is carried in when the bed is being emptied ?—Yes.

22163. That is where the oxygen comes from ?—I think so.

22164. Part of the solids are oxidised when the bed is full, and part of the retained liquid when the bed is empty ; has that been proved or is it merely inferred ?—It is inferred from the general facts gathered.

22165. Do you think that the choking of your beds is due to any extent to the presence of iron—to your exceptional conditions in Leeds. Would beds elsewhere, where there is less iron, choke equally quickly ?—I will not say equally quickly.

22166. Do you get much oxide of iron ?—Oh yes, in some cases we have found the bed material cemented together in large blocks.

22167. By the iron ?—By the iron.

22168. So that after all, your answer with regard to the lasting of the beds cannot be taken as general, but only as applying to Leeds ?—I only mean all these answers to apply to the conditions prevailing in Leeds.

22169. In your answer to Question 22024 you say that the depth of the filter should vary according to the amount of solid in the liquid treated. Well, that is a very important point ; has that been proved definitely with various amounts of solid ?—Yes, I think so ; we have tried screened sewage, septic tank effluent, ordinary settled sewage containing approximately the same amount of suspended matter as septic tank effluent, and clarified sewage ; we have tried those four on continuous filters, and to get what might be looked upon as equal final results within experimental limits we have had to have different depths of bed material.

22170. So that it comes to this,—that the difficulty of purifying sewage is the difficulty of purifying it from solid matter ?—The great difficulty is in purifying it sufficiently from solid matter.

22171. And if the solid matter is removed it becomes a much simpler problem ?—There is no difficulty at all then.

22172. In answer to Question 22027 you say the feed should if possible be continuous. Again, have you any definite proof of that ; have you tried both ?—We have tried both.

22173. On the Whittaker ?—On the Whittaker.

22174. And do you find when you have rushes that it does not sprinkle ?—We find when we have intermittent feeding, the arm stops at one place until it gathers momentum to enable it to swing round again.

22175. It forms channels, no doubt ?—Well, it gets washed through at that particular portion of the bed.

22176. I wish to refer again to Question 22031. Can you give any details as to the filter that you use without that side aeration : was it a large experiment ?—12 feet square, 10 feet deep, and the walls were blank, and the only aeration was a 6-inch valve at the bottom of the filter.

22177. What size of material—coarse or fine ?—About 3 inches diameter—coke.

22178. Is that what we saw as the continuous filter—the Leeds filter?—The first one, I daresay it would be.

22179. In answer to Question, 22044, at what temperature have you carried out the aeration test ?—Laboratory temperature.

22180. Ordinary temperature ?—Without dilution of the effluent at all.

22181. (*Major-General Carey.*) Question 21972, referring to a comparison of the results of storm water filtrates, the storm water in the experiment of March, 1905, was precipitated and filtered at the rate of 1,200 gallons per square yard ?—Yes.

22182. But in the second experiment at the rate of 500 gallons per square yard ; it was only screened before treatment on filters ?—That is so.

22183. Therefore the more favourable result was produced at considerably greater cost ?—I hardly think you can compare them in that way. The experiment on the special storm filter was supposed to follow the recommendations of the Local Government Board, that is to treat three volumes on your ordinary filters, and the remaining three volumes on special storm filters. I here show that if precipitation is included in the general method of purification for a works, that if all the storm water were settled in the ordinary precipitation tanks, then it can all be treated on the same filters as are used to treat the normal flow of sewage without having recourse to a further set of storm filters.

22184. That presupposes having tank capacity sufficient to treat the whole of your sewage and storm water ? —Certainly.

22185. Now, Question 22016, you give an example of the way in which loss of capacity occurs. In a primary bed working under ordinary conditions the capacity in that bed is very rapidly reduced per annum. In two years it would be choked altogether, or the capacity would be *nil* ?—Before you come to that point you would find the difficulty cropping up of getting the liquid into the filter.

22186. You would not get anything in ?—I mean to say the surface gets so clogged that though you may have an apparent water capacity it would take you so long filling your bed that the bed is useless.

22187. Quite so. Now, I want to know whether you would work that bed to the extreme limit, or would you take the materials out and wash them at a certain intermediate stage ; when the capacity is being reduced at that rate how are you to regain capacity ?—

Well, you cannot do it by resting. You must do it by washing the bed and replacing the material.

22188. Would you let the bed go on until it became impossible to work it any longer, or would you take it in the intermediate stage, and take out the materials and wash them ?—That is a point I can hardly answer.

22189. As far as I can make out the cost per acre bed was at 2s. 5d., which works out to about £600 per acre. Would you take it rather under that if you had to introduce fresh material ?—You mean plus that ?

22190. Or if you had to introduce fresh material ?—It would cost us at Leeds about 4s. or 5s. per cubic yard for fresh material.

22191. You mention 2s. 5d. as the actual cost ?—That is for washing only.

22192. In any scheme of biological treatment it would be always necessary to provide a considerable margin of area beyond what is actually required for the treatment in order to rest the beds, is not that so, whether contact beds of percolating filters ?—You certainly want a little elasticity in your scheme, but I do not think you need it to the extent of having a large surplus.

22193. If you rest the percolating filters once a month ? —But I do not rest them at all.

22194. I thought you did rest them ?—No, I rest contact beds once a month.

22195. But you said the percolating filters ?—Not now that I am treating storm waters; they are working day and night without any rest at all.

22196. (*Colonel Harding.*) When you are treating septic effluent do you not work them day and night for several years ?—Yes, only stopping when storms were on. We do not treat storm waters on them.

22197. (*Major General Carey.*) This is what I am referring to; Question 22036, such a filter—you are referring to percolating filters—will continue to treat, a filtrate containing about eleven parts per 100,000 of solids for a period of about one month before it becomes necessary to stop the flow on it ?—That is referring to the small straining filters for taking the solids out of the continous bed.

22198. It does not refer to the continuous filters ?—Not to the continuous filter but to the straining filter afterwards.

22199. (*Sir William Ramsay.*) May I ask one further question before we pass on. You have considerable experience, I suppose of the sprinklers for putting sewage on to the filter bed ?—I know one or two forms.

22200. Do they require very frequent picking out of the holes; does it amount to much labour ?—At Leeds we make the holes very large; we make them larger than they are delivered to us by the makers; in that case we have to clean them about once a day.

22201. What do you call large; what diameter ?—In the case of the large continuous filter we have there they will be half an inch wide at the end of the arm, the end away from the centre, going down to about $\frac{3}{8}$ inch at the centre.

22202. And these have to be picked out once a day ? —We do it by rodding the arm out.

22203. From the inside ?—Yes, we send a rod up with a lump of waste on the end.

22204. Does it take long; do you take off the arm ? —No, we can take off a cap at the end.

22205. Push the whole of it back into the centre ?—Yes.

22206. Does it take long ?—No, about ten minutes will do it perfectly.

22207. The whole of them ?—One.

22208. One rod ?—Well, we have only two arms to deal with.

22209. I see. What I want to get at is, is it conceivable that a sprinkler can be used without a very great deal of mechanical labour being required to clean it daily ?—Wherever you have holes in a sprinkler arm you will have labour.

22210. Is it serious ? We were told by one of our witnesses that there is a plan of sprinkler for continuous filter which is probably to be adopted over acres. Does it not involve an enormous amount of mechanical labour in cleaning those holes which he told us were as small as one-sixteenth inch rising in size ?—One-sixteenth is too small; they would clog easily.

22211. It would be a very expensive method ?—I think if you have large holes it will not be a very serious cost; you will have to have men on the works.

22212. They might just as well be doing that as anything else ?—They might fill up their time in that way.

22213. (*Mr. Stafford.*) Referring to your answer to Question 21966 how do you estimate the strength of the sewage; you speak of the sewage at Leeds as not strong; have you any particular method of estimating the strength of it ?—I state in the answer to Question 21966 that it is not strong with regard to organic impurity. That is as far as I prefer to go.

22214. Yes, but you have no particular test or method of estimating the strength ?—No.

22215. In Question 21972, there is an analysis; is this the analysis of the effluent of the storm filter ? —Yes, with the storm water streaming through it.

22216. Do you find that the nitrates come out in a storm water filter when the beds have been flooded ?— I do not understand the question.

22217. Do you find that a good deal of the nitrates come out in large quantities when the beds are flooded ?— Well, you see by the analysis we get nitrates.

22218. I see you get nitrogen 0·624 ?—Yes, that is the average of a great number of experiments. Of course, the nitrates, I have no doubt, are formed when the beds are resting between storms.

22219. Is that continuous or does it come in rushes ?— The storms ?

22220. The amount of nitrates coming out; does it come out in rushes at the beginning or is it continuous ?— Oh, it is continuous, gradually tailing off as the storm continues.

22221. How long does it continue ?—I have never found the effluent without nitrates.

22222. In the same proportion ?—It would start at a higher value than this and gradually get less.

22223. In answer to Sir William Ramsay about the cost of washing and the cost of replacing new material, I understood you to say that the cost of washing was about 1s. 6d. per cube yard; is that it ?—I pay for it 2s. 5d. without mechanical appliances.

22224. And the cost of the new material was about 5s. ? —About 4s. to 5s.; that is to grade and place in the beds.

22225. Do I understand that there would be that amount of saving, the difference between 1s. 6d. and 2s. 4d. and 5s. in your method ?—No, because in washing you will certainly wash away some of the fine broken down material which you will have to replace.

22226. I understand that, but the amount of washed material; there will be that amount of saving on the washed material; the difference between 1s. 6d. and 5s ?— No, the difference between 1s. 6d. plus the cost of the material necessary to be added to bring the bed up to its old level, and 4s. and 5s.

22227. Yes, but still there is a decent saving ?—Oh, there is a distinct difference, certainly, on the side of washing the material if it can be done for 1s. 6d. on the large scale.

22228. (*Colonel Harding.*) It was suggested yesterday by a witness that washing was not only not prohibitive in cost but that it was actually desirable for new material, that there was a positive advantage in washing of new material, with the idea of getting out of it broken down portions of the material, and selecting by that means the better sort to be kept in the bed. Then it was pointed out to us by a witness, who had carried it out on a fairly large scale, that after washing material when the bed has become to a certain extent choked you wash away the broken down portions of the material, that what is left is far better than the original material. I think that your view is that it is practicable to wash materials ?— Oh, yes.

Mr. W. H. Harrison, M.Sc.

11 May 1905.

22229. And that you would get a sufficient quantity of material after the washing to fill the greater part of the bed ?—Certainly.

22230. You would not require at most more than, shall we say, a quarter of new material ?—I should not like to give any figures.

22231. Well, you have tried some experiments, can you not express an opinion ?—Yes, but the material I washed had been well graded and well sifted before it had been used, and it had been used in a contact bed before I washed it.

22232. You had no opportunity at Leeds of trying any extensive experiments in the washing of filtering material ?—No.

22233. Turning back for a moment to the point raised by Sir William Ramsay as to the presence of iron in Leeds sewage, and the fact that it makes the Leeds condition somewhat special, could you tell us to what extent iron comes down in the Leeds sewage. Could you give us a figure for instance expressed in metallic iron as to the amount of ferrous sulphate that comes down ?—In broad figures we should get about 4 tons of metallic iron a day coming down with the sewage ; that is, roughly speaking, about 4 grains per gallon.

22234. That, of course, is a very considerable quantity ? —Yes.

22235. And must to some extent modify the results obtained at Leeds in comparing them with the results obtained where iron does not exist in the sewage ?—Oh, without doubt.

22236. On the other hand there are many towns, as in Leeds, where a good deal of such matters come down in the sewers ; one might instance Birmingham, Sheffield, and many others ?—Yes, that is so.

22237. Now, with regard to the presence of iron, which would appear to be the most convenient form of filtration, contact filtration or percolating filtration ?—Percolating.

22238. And probably because you have found that in the contact filtration the iron deposit has acted as a cement ?—That is so with regard to contact filtration.

22239. Cementing together parts of the material so as to make in effect one block ?—Yes.

22240. On the other hand in percolating filters the iron which comes out of solution into suspension takes a granular form and comes out in the filtrate ?—That is so.

22241. Is that due, do you think, to the better oxidation arising in the percolating filter which changes the iron from the ferrous into the ferric state ?—There is no doubt that iron is better oxidised in its passage through a percolating filter.

22242. Is ferric sulphate less soluble than ferrous ?—(*Sir William Ramsay.*) It is the other way round, (*Col Harding.*) But in fact the iron coming out in the percolating filter is in the ferric state ?—Yes, but in a basic-ferric state ; it is insoluble altogether.

22243. Insoluble ?—Yes, in the percolating filter effluent, which is giving satisfactory results, there is never more than a trace of iron in solution. Immediately the bed begins to fall off then iron begins to appear in solution.

22244. Then at Question 21962 * you alluded to the fact that the effluent from contact beds at Leeds were apt to be strongly yellow and often very unsightly, giving rise to flocculent subsequent decomposition. Had these observations applied rather to the time when you were using your contact beds for more or less crude sewage ?—Oh, that is so.

22245. When you were using on the contact beds septic effluents that would not arise ?—I have never had it yet.

22246. And in fact the effluents from contact beds when you were using septic effluents were extremely good ?—Quite as good as I have obtained from any method of filtration.

22247. There was no yellow colour and no subsequent decomposition and flocculent matter ?—None at all.

22248. You found that passing sewage through a septic tank caused a very great improvement in that respect ?—Yes.

22249. Passing on to the question of storm waters and your answer to Question 21970 you give there certain analyses ; in the first instance, four periods of storm, each of which had lasted about 20 hours. Are those averages spread over the whole duration of the storm, or are they simply averages of one analyses taken in regard to each ?—Oh, no, they are averages for each storm.

22250. What I wanted to get at was this, are the averages from analyses taken, say, at the beginning and at the end of the storms ?—In fact during the storms, and were taken away every half hour.

22251. These are really over the whole duration of the storms ?—Yes.

22252. Taking these over the whole duration, you observe that on the average the storm waters practically contained the same amount of suspended matter as ordinary sewage ?—That is on the average.

22253. That is taking it on the average ; taking simply at the beginning, the middle and end of the storm ?—Yes.

22254. You do not suggest that the amount of suspended matter at the beginning of a storm would not be much greater ?—I think the tendency of these analyses go to show that.

22255. The beginning of a storm, the very beginning of it, does bring down a great deal of suspended matter ? —Yes.

22256. And the analyses which you have given, which immediately follow your answer to Question 21970, go to show that when you have withdrawn the suspended matter from storm waters you have to deal with the liquid which is greatly less impure than ordinary sewage which has been precipitated ?—Yes.

22257. Roughly speaking about half the strength ? —Yes.

22258. The settlement of the suspended matter in storm waters is the essential treatment to be followed ; is it not in your opinion ?—To remove the suspended matter, yes.

22259. Then, when that has been done, if it is necessary to carry the purification further, is it more conveniently done on contact or on percolating beds ?—On percolating beds.

22260. Why ?—On contact you are limited to the number of fillings you can give per day. Percolating is simply a case of increasing the flow on to the filter.

22261. Then, on contact beds, if you increase the fillings too far there would be no adequate period of rest and of aeration ?—No.

22262. If you exaggerate the treatment on contact beds to the point of streaming storm water through them, there is practically no biological action at all ?—There would not be after the process had been continued for some time.

22263. What you mean is that during the period of rest the bed will have accumulated nitrates and so on, but those will soon get washed out ?—Yes.

22264. And after that there will be probably no oxidation ?—That is so.

22265. The experiments that you tried at Leeds with streaming filters as a single process for the treatment of storm waters did not appear to have given very good results ?—They are not nearly so good as the treatment of precipitated storm waters on the continuous filter.

22266. Even with regard to the withdrawal of suspended matter ?—That is so.

22267. Of course, on the other hand there is this to be said that the sedimentation of storm waters involves the production of a great deal of sludge which is always a trial and a trouble, is it not ?—Yes.

22268. I want to ask you a question which you may not be able to answer because possibly you may not have given attention to it, but it would be interesting to us to know if you are able to tell us in regard to Leeds what would be the proportion of storm waters in a year and the dry weather flow in a year. For instance if you take this to be 100 what figure would you have to add to that to represent the storm waters in a year ?—I could not tell.

22269. I am under the impression that about 50 per cent.; but of course, if you have not at hand the tables do not attempt to answer ?—No; I have here a table showing the average number of days on which various amounts of rain fell.

22270. That is the only way at which you can get at the information I want ?—Extending over a period of four years.

22271. Do those tables enable you to answer my question ?—I do not think so. The average number of fine days, 199; number of days that rain fell to only 1·1., 85; the number of days under 2 inches.

22272. I am afraid your giving us those figures will not help us ?—No, I am afraid not.

22273. Because it is necessary to digest them and calculate out the conclusion. At Question 21974 you give us a very interesting result of experiments in stagnant settlement of sewage, and it would appear that stagnant or quiescent settlement of sewage is remarkably effective as compared with flowing settlement, and in the first half hour, not to say in the first quarter hour, the bulk of the suspended matter is thrown down ?—That is so.

22274. It would seem to be possible by quiescent settlement of sewage and a comparatively small area of tanks to reduce the suspended matter down to 8 or 9 parts per 100,000 ?—Yes.

22275. And the reason why quiescent settlement is not universally adopted is probably the fact that there is a loss of head equivalent to the depth of the tanks, and that in most cases that would involve pumping up again ?—That is so.

22276. But where the levels permit you think highly of the quiescent settlement ?—It certainly gives a very good result and should be borne in mind.

22277. In the case of quiescent settlement, of course the idea would be to empty the sludge out every 24 or 48 hours ?—To clear out the sludge, yes

22278. You have not tried any experiments at all in this direction to septicise, not the sewage, but the sludge ?—Not with success.

22279. As a fact you have not tried an experiment at all ?—No, I tried to get septic conditions in the sludge and I could not; I gave it up.

22280. Tell us about that. It would be rather interesting, how did you try ?—I took an ordinary settlement tank, filled it full of water and ran in sludge produced from a small quiescent settlement tank, and I inoculated the tank with septic sludge out of our ordinary septic tank. I never got septic conditions occurring.

22281. In what period of time ?—Two months.

22282. But did you not, once, in some earlier evidence that you brought before us, tell us a case in which you had had a settlement tank entirely filled up with deposit, and you were unable at the time to empty it, and you let it alone for a month or more and the septic conditions developed rapidly, and the matter which at first stood up in islands on the surface of the water gradually settled down and became more or less liquid and septic ?—That undoubtedly did occur, but in that case I induced septic action by running continuously through it a small flow from a septic tank.

22283. A very small flow indeed, was it not ?—A very small flow.

22284. On this point of treating sludge septically, would you not empty successive tanks for a flow going through, and when the septic action had been once set up would it not continue ?—I would hardly like to say.

22285. You have not the necessary information to answer ?—No.

22286. But you think probably it is a point that might be worth investigation ?—It is certainly a point worth attention.

22287. In Question 21994 you referred to the effect of atmospheric temperature upon septic action and you give us details of a small experiment in which you gauged the gases given off from a septic tank from a certain area ?—Yes.

22288. And in summer you found that the gases given off are represented by the figure 37; in winter by the figure 13 ?—13.

22289. That is a striking difference in the production of gas ?—Yes.

22290. Could it be in any way accidental, think you ?—No, I do not think so.

22291. You think it was due to the difference in temperature ?—There certainly is a large difference in the amount of gas given off from a septic tank in summer and winter.

22292. On the other hand, you did not find, did you, in your experiments, that where you heated septic sewage you brought about greater septic action ?—Oh, in that case I heated the sewage going into a series of separate tanks, and got very little difference between the results in any case.

22293. You had a number of septic tanks, one of which was at the normal temperature ?—Yes.

22294. And others at increasing temperatures due to the injection of steam ?—Yes.

22295. And the last one was at the temperature of 100° F. ?—Yes.

22296. And in that case you did not find more digestion of suspended matter ?—No, certainly not; I think it was rather less than the normal tank.

22297. It seems a result which is a little out of harmony with the other one about the summer heat producing more septic action than in winter ?—It may be due to the injection of steam; the injection of steam into the sewage, going into the tank, may have had a sterilizing effect upon the sewage.

22298. But from your observations with this experimental tank and with the large area of septic tanks you had at Leeds, you have very little doubt that in summer the septic action is greater than in winter ?—Taking the gas as the factor, yes.

22299. A special feature of your experiments with percolating beds at Leeds appears to have been the abandonment of fine material and the subsequent successful use of coarse material ?—Yes.

22300. Something was said to you in cross-examination just now about the choking up of percolating filters; that choking up you only found when the material was too small ?—Was disintegrated.

22301. Or where by disintegration it had become too small ?—That is so.

22302. Given a material which will not readily break down and which is sufficiently coarse, a percolating filter may go on almost indefinitely, and it is only limited, is it not, by the degradation of the material ?—So far that has been my experience.

22303. In the case of a percolating filter as compared with a contact filter, no doubt the question of degradation applies in both sorts of filtration, only in the case of contact filtration you have the additional difficulty of the accumulation of undigested matter ?—Yes.

22304. Whereas in a coarse percolating filter, may I take it that the undigested matter does not in any way tend to accumulate; it passes through the filter ?—Not if there is disintegration occurring.

22305. No; but I am assuming that you are getting a material which is fairly free from disintegration; it is merely a question of theory at present ?—In that case there ought to be very little accumulation, at least permanent accumulation.

22306. You remind me of a point of some importance to bring out and that is this; in flowing at the dry weather rate through a percolating filter there is a pretty steady accumulation of suspended matter in the filter ?—Yes.

22307. But it does not remain there permanently ?—No.

22308. It comes out does it not ?—We get an increase in the amount of suspended matter in the effluent about twice a year.

22309. Tell us about these occasional flushes and what you attribute them to ?—I think I answered that, I have given that in answer to one of the questions given here.

Mr. W. H. Harrison, M.Sc.

11 May 1905.

22310. Perhaps you will just briefly repeat it, will you ? I think you said it was due to the developemnt of certain forms of life at certain periods. What I wanted you to do was to precise a little more what those forms of life were ?—In reply to Question 22037 the answer is given there.

22311. I want you more particularly if you are able, to tell us what the special forms of life were ?—Worms chiefly and a larger larva.

22312. Such as ?—Well, we get the larva of certain beetles in the effluent and psycoda.

22313. Immense numbers of them ?—Yes.

22314. And you find the action of these forms of life is to disturb the matter deposited on the surface of the material, and having so disturbed it to bring it out by the flow ?—The only reason why I say that is that the flushes occur at a period when you would expect them, if this idea is correct.

22315. Then matter left behind by the normal flow of a percolating filter, provided the filter is built of sufficiently coarse material ultimately comes out either by the occasional flushes such as you have referred to, or by increased flow at storm times ?—That is so.

22316. And therefore the main difficulty in regard to the material of percolating beds is the getting of a material which will not rapidly disintegrate ?—That is the great difficulty.

22317. I think you found that the storm destructor clinker at Leeds was extremely friable ; some parts of it ? —Oh yes ; a bed built of very coarse material only lasted two years.

22318. The great thing therefore is to find a material which shall be, as far as possible, permanent ?—Yes.

22319. I understood that you were going to try at Leeds some experiments with spherical material of hard burnt clay ?—I have some on the works now but not sufficient to start an experiment.

22320. You are expecting to start an experiment soon ? —As soon as I get the material.

22321. You will probably expect with hard burnt clay there would be comparatively little degradation ?—Yes, I expect to have the same result that we get with a bed made of gravel.

22322. You get considerable permanence of material ? —Yes.

22323. And that is a vital point ?—It is the great point.

22324. Another interest which attaches to the experiment that you are about to try is that the material is spherical ?—That is so.

22325. It is in balls ?—That is so.

22326. About what size ?—Two inches.

22327. And what is the advantage that you see in the use of spherical material in regard to the air spaces ?— I foresee that we shall have an amount of internal surface in the filter, larger than if we used an irregular surface, like broken clinker ; and air spaces.

22328. And the air space ; if the form of each piece of the material is the same the air spaces will also be alike ? —Yes.

22329. And all equally large ?—Yes.

22330. In reply to Question 22038 you give some interesting tables—the result of treating precipitated storm waters upon percolating filters of different depth, but when you put partially settled storm waters or unsettled storm waters upon the percolation beds the results were more or less unsatisfactory, because the suspended matter coming out had not remained long enough in the filter, had it ?—That is so. The matter washed out from a filter treating screened storm water and was putrescent in character.

22331. Dr. Stafford asked you something about the washing out of nitrates from percolating filters at times of storm : if much suspended matter is brought to the filter in times of storm there would be almost a complete disappearance of nitrates very soon, would there not ?— I have never found them disappear in storm water effluent.

22332. Not entirely, but they have been greatly reduced ?—Greatly reduced.

22333. And much more reduced where you have suspended matter ?—Yes.

22334. There is an interesting feature in these tables which I would like to call attention to, and that is this : For instance, if Table IV (c) is looked at, it will be seen that the filtrate from the precipitation bed, including, I take it, the suspended matter coming out with it, only takes up 13 per cent. of the dissolved oxygen ?—Yes, that is so.

22335. That would be, of course, after 24 hours and after saturation ?—Stand 24 hours in a laboratory.

22336. And that is a very small proportion ?—Yes it is a very low figure for an average.

22337. With a 6-feet bed, working at 100 gallons per square yard, I see the result only took up 10 per cent. of dissolved oxygen ?—I have had particular filtrates that have taken up none.

22338. Then one of the features of the percolating bed filtration at Leeds was the great amount of dissolved oxygen contained in the filtrate itself without adding any ?—In a continuous filter effluent ?

22339. Yes.—Yes ; they are usually saturated.

22340. Almost saturated ?—Yes, contact bed effluents are rather under saturation point.

22341. That is a distinct advantage ?—That is a general rule.

22342. In Question 22027 you refer to the effects of intermittence of flow upon percolating filters. You are asked whether the feed of a percolating filter should be intermittent or continuous, and you suggest that it should, if possible, be continuous, as any intermittency tends to produce a filtrate fluctuating in quality. The expression of that opinion must be based, is it not, upon the particular kind of sprinklers you have been using at Leeds ?—Certainly ; I do not speak with regard to any other sprinklers.

22343. You have been using sprinklers which work intermittently, and I think you said to Sir William Ramsay, or someone, that when they started and stopped there was irregularity of distribution ?—Yes.

22344. But if you had upon very large rectangular filters, a distribution, a continuous flow, which passed along the surface of the filter from end to end, and then returned, you would get intermittency without irregularity, would you not. If you have no experience, do not attempt to reply ?—I could not say.

22345. You do not mean, do you, that intermittence *per se* is a bad thing ?—No.

22346. On the contrary, perhaps, have you not found certain advantages in intermittence ?—Yes ; the objection is that the arm is delivering sewage at a fixed place until it gains momentum to move round.

22347. It is simply the fact of your own sprinklers having been more or less unsatisfactory ?—That is so.

22348. That leads you to say that it is desirable, as far as possible, to have a continuous flow ?—Yes.

22349. But assuming the continuous flow would not be open to the disadvantage you refer to, the intermittence has a certain advantage, has it not ?—Yes.

22350. In regard to the growths ?—Yes, we find with the intermittence they are not so thick.

22351. You find that by intermitting the flow a few minutes each time, the growth on the surface is reduced ? —Yes.

22352. On the other hand, the intermittence with very coarse percolating filters is a very great disadvantage ?— Yes, you get intermittency in the effluent then.

22353. In a percolating filter where you have intermittence on the surface, intermittence of flow, possibly working for one minute and then standing for three minutes ; does that appear much in the outflow at the bottom, or is there a gradual equalisation of the outflow at the bottom ?—With coarse material you can see a fluctuation in the amount coming out.

22354. But it is not a very great fluctuation even with coarse material?—No. If you have fine material of course you see no difference in the rate of flow from the bed.

22355. What is the speed of passage through a coarse percolating filter 9 feet deep?—If dye such as fluorescein is put in the sewage going on to the filter, it will appear in the filtrate within two minutes if the bed is made of coarse material.

22356. That is, discolouration appears?—Yes.

22357. So that the action of percolating filters on dissolved impurities is marvellously rapid?—Yes.

22358. On the other hand the action upon suspended matters going through the filters is very much more slow, is it not?—I should judge it would take the solids about a month to pass through an ordinary coarse filter.

22359. That is the reason why probably you think storm waters ought not to be left really on filters of that kind, if they bring to the filter much suspended matter, because they wash it through much too fast?—They wash it through much too fast, but if there is an efficient straining filter after such a filter, I do not see that there is any disadvantage.

22360. Provided you have a subsequent process?—Yes.

22361. Then briefly, in regard to both kinds of filtration, it appears very important, provided there is a local opportunity of dealing with the sludge, to settle solids out as much as possible?—For reasons of purification.

22362. In either case?—Yes.

22363. And for other reasons surely; the life of the contact beds for instance?—Even with contact beds treating a very small amount of suspended matter down to 8 grains per gallon, I have still had a remarkable rate of clogging occurring.

22364. Yes, but I think you have told us also that much of that was due to disintegration and consolidation?—Yes, consolidation, but I have had it occur also in the case of the small Cameron plant.

22365. But the quantity of suspended matter going on in those cases is considerable?—It is about thirteen on the average.

22366. But supposing you put clarified effluent on contact beds, is the life of the bed likely to be considerable?—Yes, much more than solid matter.

22367. In regard to contact beds, the question is this, sooner of later you are bound to reach a condition when you will have to wash or renew the material?—Yes.

22368. But if you put on the contact beds effluents which do not contain much suspended matter, they may last for many years?—I see no reason why they should not.

22369. Putting crude sewage on beds you find a primary bed absolutely choked in two years?—Yes.

22370. You have formed the opinion that the cost of renewing the material, or washing the material, would not be a prohibitive one, have you?—I could not answer that; it depends on the financial state of the town.

22371. It is a question of engineering whether it is cheaper to have a large tank area and to spend money on chemical precipitants, to press sludge and deal with a large quantity of sludge, or whether it is cheaper to deal with a large part of the suspended matter on the filter, and wash out or renew the material more often?—I think it is a question as to whether the corporation or municipality will rather face a large annual cost or a great capital cost.

22372. It is a question largely of finance?—Yes.

22373. (*Sir William Ramsay.*) I want to refer to your answer to Question 22024 where you speak of the depths of the filter. We have heard about that already; I want to ask, would it come to the same thing if you had a shallower filter at a slower rate? This is important as a question of levels; in many works it would be impossible to make a 9 feet or 10 feet filter. Would it be possible to have a 5 feet filter, making the sewage pass over at half the rate?—Yes, I think the rate of flow on to a filter does make some difference. In my answers to certain questions you will find that.

22374. But not to that particular one, I think?—In 22038, Tables IV. (*a*) and (*c*) show the results obtained from the same filter, six feet deep, and treating sewage at the rate of 100 gallons per square yard. Recently it has been treating 200 gallons per square yard; there is a slight difference in the result obtained.

22375. Would it compensate for want of depth—you see the importance of it from the point of view of pumping?—Yes.

22376. Is it possible to overcome this difficulty where pumping is not admissible, in a small sewage work for example, by increasing the area of the filter and lessening the rate?—With regard to liquid containing a small amount of suspended matter, I think that would answer, but I should not like to give any opinion with regard to a filter treating crude sewage. I do not think there that you could get a good effluent with much under 7 or 8 feet even with a very reduced flow.

22377. (*Colonel Harding.*) But if in a certain situation it were not possible to get percolating filters beyond a given depth, the circumstances might be made to fit that depth by reducing the suspended matter going on to the filters?—Certainly.

22378. That would be the best way of meeting it; instead of reducing the flow you would reduce the suspended matter?—That is so.

22379—80. Then a filter of reduced depth would give adequate results?—Yes.

LEEDS.

Appendix to Evidence of Mr. W. H. Harrison.

Tables showing average analyses of sewage, tank liquor, and filter effluents at Leeds, January, 1903—December, 1904.

PROCESSES OF TREATMENT:

(*a*) Chemical Precipitation.

(*b*) Open Septic Tanks and Double Contact Beds.

(*c*) Exeter Septic Tank and Single Contact Beds.

(*d*) Continuous Filtration, viz.:—

Leeds Filter.

Whittaker Filter.

Ducat Filter.

January, 1903.

LEEDS.

SEWAGE—

Average Analysis of Sewage.

	Best.	Worst.	Average.
Ammoniacal nitrogen	1·93	3·53	2·53
Albuminoid nitrogen	·617	1·18	·840
Oxygen absorbed from $KMnO_4$ in 4 hours	7·79	8·24	9·79
Suspended solids	—	—	47.7
Soluble solids	—	—	101·3

Number of samples analysed for the average = 4.

PRECIPITATION PROCESS—

Amount of sewage treated during the month - 400¾ million gallons.
Amount of lime used during the month - 68 tons 9 cwts.
Amount of sludge dealt with during the month - 8,152 tons.
Amount of sludge removed from the works - 275 tons.

Average Analysis of Tank Liquor.

	Best.	Worst.	Average.
Ammoniacal nitrogen	1·56	1·90	1·80
Albuminoid nitrogen	·345	·444	·367
Oxygen absorbed from $KMnO_4$ in 4 hours	3·72	6·67	4·48
Suspended solids	—	—	19·0
Soluble solids	—	—	112·1

Number of samples analysed for the average = 4.

OPEN SEPTIC TANKS AND DOUBLE CONTACT PROCESS—

Average daily flow through the tanks - 24 hour flow.
Amount of septic sludge removed during the month - 2,346 tons.
Amount of sewage treated by the septic tanks - 67,410,000 gallons.

Average Analysis of Tank Liquor.

	Best.	Worst.	Average.
Ammoniacal nitrogen	·857	1·09	·953
Albuminoid nitrogen	·188	·410	.264
Oxygen absorbed from $KMnO_4$ in 4 hours	1·90	3·74	3·12
Suspended solids	—	—	10·5
Soluble solids	—	—	89·5

Number of samples analysed for the average = 4.

Number of times primary bed was filled during month - 33.
Number of times secondary bed was filled during month - 33.
Amount of tank liquor treated per cube yard per 24 hours - 30·76 gallons.
Amount of tank liquor treated during the month - 2,111,000 gallons.

Average Analysis of Final Effluent.

——	Best.	Worst.	Average.
Ammoniacal nitrogen	·264	·260	·260
Albuminoid nitrogen	·041	·076	·054
Nitric nitrogen	1·90	2·45	2·40
Oxygen absorbed from $KMnO_4$ in 4 hours	·202	·531	·395
Dissolved oxygen taken up in 24 hours	—	33%	16%
Incubator test { Before	·10	·32	·185
Incubator test { After	·21	·20	·171
Suspended solids	—	—	heavy trace.

Number of samples analysed for the average = 3.

EXETER SEPTIC TANK PROCESS—

Average daily flow through the tanks - 24 hours' flow.
Amount of sludge removed during the month - nil.
Amount of sewage treated by the process - 583,609 gallons.

Average analysis of tank liquor—

Ammoniacal nitrogen	1·20
Albuminoid nitrogen	·350
Oxygen absorbed from $KMnO_4$ in 4 hours	2·85
Suspended solids	14·1
Soluble solids	88·5

Number of samples analysed for the average = 1.

Number of times beds were filled during the month - 193
Amount of tank liquor treated per cube yard per 24 hours - 45 gallons.

Average analysis of final effluent—

Ammoniacal nitrogen	·419
Albuminoid nitrogen	·128
Nitric nitrogen	1·47
Oxygen absorbed from $KMnO_4$ in 4 hours	·88
Dissolved oxygen taken up in 24 hours	83%
Incubator test { Before	·21
Incubator test { After	·10
Suspended solids	2·85

Number of samples analysed for the average = 1.

CONTINUOUS PROCESSES—

EXETER SEPTIC TANK PROCESS—

Average daily flow through the tanks - 24 hours' flow.
Amount of sludge removed during the month - none.
Amount of sewage treated by the process - 440,000 gallons.

Average analysis of tank liquor—

Ammoniacal nitrogen	1·17
Albuminoid nitrogen	·182
Oxygen absorbed from $KMnO_4$ in 4 hours	2·41
Suspended solids	11·5
Soluble solids	83·5

Number of samples analysed for the average = 1.

Number of times beds were filled during the month - 184
Amount of tank liquor treated per cube yard per 24 hours - 34
Average analysis of final effluent—

Ammoniacal nitrogen	·294
Albuminoid nitrogen	·094
Nitric nitrogen	1·90
Oxygen absorbed from $KMnO_4$ in 4 hours	·89
Dissolved oxygen taken up in 24 hours	28%
Incubator test — Before	·30
Incubator test — After	·37
Suspended solids	4·0

Number of samples analysed for the average = 1.

May 6th, 1904. *W. H. Harrison.*

LEEDS—*continued.*

SEWAGE— *Average Analysis of Sewage.* September, 1903.

——	Best.	Worst.	Average.
Ammoniacal nitrogen	1·60	1·99	1·73
Albuminoid nitrogen	·469	·632	·499
Oxygen absorbed from $KMnO_4$ in 4 hours	8·24	13·6	10·6
Suspended solids	—	—	104·0
Soluble solids	—	—	107·0

Number of samples analysed for the average = 3.

PRECIPITATION PROCESS—

Amount of sewage treated during the month - 438 million gallons.
Amount of lime used during the month - 72 tons 8 cwts.
Amount of sludge dealt with during the month - 9,972 tons.
Amount of sludge removed from the works - 246 tons.

Average Analysis of Tank Liquor.

——	Best.	Worst.	Average.
Ammoniacal nitrogen	1·45	1·59	1·51
Albuminoid nitrogen	·222	·247	·247
Oxygen absorbed from $KMnO_4$ in 4 hours	3·24	5·52	3·87
Suspended solids	—	—	6·1
Soluble solids	—	—	90·0

Number of samples analysed for the average = 3.

OPEN SEPTIC TANKS AND DOUBLE CONTACT PROCESS—

Average daily flow through the tanks - 24 hours flow.
Amount of septic sludge removed during the month - none.
Amount of sewage treated by the process - 71,160,000 gallons.

Average Analysis of Tank Liquor.

——	Best.	Worst.	Average.
Ammoniacal nitrogen	·932	1·12	·983
Albuminoid nitrogen	·227	·340	·274
Oxygen absorbed from $KMnO_4$ in 4 hours	4·04	6·24	5·40
Suspended solids	—	—	17·1
Soluble solids	—	—	83·5

Number of samples analysed for the average = 3.

Number of times primary bed was filled during month - 38
Number of times secondary bed was filled during month - 38
Amount of tank liquor treated per cube yard per 24 hours - 33·4 gallons.
Amount of tank liquor treated during month - 2,226,000 gallons.

Average Analysis of Final Effluent.

——	Best.	Worst.	Average.
Ammoniacal nitrogen	·099	·124	·111
Albuminoid nitrogen	·027	·031	·029
Nitric nitrogen	1·51	2·60	2·05
Oxygen absorbed from $KMnO_4$ in 4 hours	·438	·385	·411
Dissolved oxygen taken up in 24 hours	16%	30%	23%
Incubator test — Before	·14	·17	·15
Incubator test — After	·14	.10	.14
Suspended solids	—	—	hy. tr.

Number of samples analysed for the average = 2.

EXETER SEPTIC TANK PROCESS—

Average daily flow through the tanks	24 hours' flow.
Amount of sludge removed during the month	none.
Amount of sewage treated by the process	563,000 gallons.
Average analysis of tank liquor—	
Ammoniacal nitrogen	1·24
Albuminoid nitrogen	·238
Oxygen absorbed from $KMnO_4$ in 4 hours	3·25
Suspended solids	9·1
Soluble solids	81·1

Number of samples analysed for the average = 1.

Number of times beds were filled during the month	232.
Amount of tank liquor treated per cube yard per 24 hours	45 gallons.
Average analysis of final effluent—	
Ammoniacal nitrogen	·588
Albuminoid nitrogen	·305
Nitric nitrogen	1·81
Oxygen absorbed from $KMnO_4$ in 4 hours	1·42
Dissolved oxygen taken up in 24 hours	50%
Incubator test — Before	1·08
Incubator test — After	·67
Suspended solids	16·2

Number of samples analysed for the average = 1.
